Abstract

Objectives: To compare the vitamin D status in schizophrenics to that of healthy controls; secondary objectives were to assess the correlation between severe vitamin D deficiency and the severity of schizophrenia symptoms and to evaluate the potential factors influencing this status.

Methods: A case-control study, conducted between March and July 2016, recruited 100 patients with schizophrenia and 100 controls with no known psychiatric disorders and matched for age and sex.

Results: Schizophrenic patients had a more severe vitamin D deficiency compared to healthy controls (9% vs. 3%). Vitamin D insufficiency was found in 28% of schizophrenic patients compared to 37% in healthy controls ($p=0.053$). BCRS and MRSS scales were significantly associated with a more severe vitamin D deficiency ($p=0.006$). We couldn't detect any association between the total PANSS score and its three subscales with vitamin D deficiency ($p>0.05$). Sun exposure, intermediate and high socioeconomic levels would significantly increase the odds of having an increased level of vitamin D as compared to low socioeconomic level (OR=1.046, OR=141.919 and OR=132.110) respectively. Higher MRSS scores would significantly increase the odds of having a more severe vitamin D deficiency by 15.2% (OR=0.848, CI 0.731 - 0.984, $p=0.029$).

Conclusion: Vitamin D insufficiency is prevalent in patients with schizophrenia. Further work is needed to answer the question of causality. Is vitamin D deficiency the result or the cause of schizophrenia? Future cohort studies may investigate the association with longer follow-up. Spreading awareness among health care professionals for routine serum vitamin D testing, along with patient education, are necessary to avoid this problem.

Keywords: Vitamin D; Schizophrenia; BCRS; MRSS; Schizophrenia symptoms

Introduction

Vitamin D deficiency has been extensively linked to a wide range of neuropsychiatric disorders, including schizophrenia [1-4]. In fact, vitamin D is involved in various brain processes including neurodevelopment, neurotransmitter expression, neurotrophic and growth factor regulation and is thought to be neuroprotective [3]. In addition to its well-known role in calcium and bone metabolism, vitamin D has been shown to be a potent inducer of nerve growth factor synthesis [5-7]. McGrath suggested that a prenatal deficiency of vitamin D might be a risk factor for schizophrenia [5].

A pathophysiological effect of vitamin D levels on schizophrenia development, with a reversible effect after correction has been postulated [8]. Studies have shown that schizophrenics tend to be born in winter/spring seasons during which the Ultraviolet rays (UVB) required to synthesize vitamin D are reduced [9,10]. In addition, schizophrenic patients are more likely to stay indoors and have reduced exposure to sunlight, hence the increased risk of low vitamin D level [3,7]. Furthermore, most schizophrenic patients do not consume enough dietary vitamin D [11,12] with the latter shown to reduce the risk of psychosis or schizophrenia [6,13]. These factors may not be causal but may arise due to confusion with independent

risk factors [8], such as ethnicity, dietary factors, sedentary lifestyle, physical activity, body mass index, urban living and socioeconomic status [7,8,14,15].

Vitamin D has also been linked to mental illnesses including Alzheimer's [16], premenstrual mood disorder [17], major depression [18] and psychosis [19]. However, the relationship between vitamin D status and brain functions is still not elucidated [19], despite some evidence of negative, cognitive [20,21] and mood [22] effects in people with insufficient vitamin D levels. A recent study showed that in schizophrenic patients, a significantly greater severity of negative symptoms was correlated with lower vitamin D status, while overall symptom severity and positive symptom severity approached a significant relationship with vitamin D status. These findings lead researchers to hypothesize that inadequate vitamin D status may account for some portion of the symptom burden experienced by schizophrenic persons [1].

Lebanon has a high prevalence of 25(OH)-D deficiency in adults and older adults [23,24] however, data regarding vitamin D levels in psychiatric patients is still lacking. Therefore, the primary objective of this study was to compare the vitamin D status in schizophrenics to that of healthy controls; secondary objectives were to assess the

correlation between severe vitamin D deficiency and the severity of schizophrenia symptoms and to evaluate the potential factors influencing this status.

Materials and Methods

Study design and participants

A case-control study was conducted at the Psychiatric Hospital of the Cross (PHC) - Lebanon, between March and July 2016. A hundred patients with schizophrenia and 100 controls with no known psychiatric disorders were recruited and matched for age and sex. The study received approval by the research and ethics committee of the hospital and participants or their legally representative provided a written informed consent before entering the study.

Patients newly admitted to the hospital, suffering from schizophrenia for no longer than ten years, diagnosed by the treating psychiatrist according to medical file diagnosis [25].

Individuals were excluded if they had any other mental illness, had a diagnosis of alcohol or substance dependence, were treated with vitamin D supplement, or had a metabolic disease that may affect serum vitamin D concentrations.

Clinical and psychiatric evaluations

Demographic (age, gender, geographic region, marital status, occupation, educational level, monthly income per house) and clinical information of the participants (diagnosis, duration of illness, medications intake at the time of the study, blood pressure, history of medical illness and family history of mental disorders) were collected from medical files. The socioeconomic status divided into three levels (low (<1000USD), intermediate (1000-2000USD), high (>2.000USD), was collected from medical files based on the income, education and occupation of each patient. The number of weekly hours of sun exposure, physical activities (indoor and outdoor) and consumption of certain foods (milk, fish, eggs, meat, fruits and vegetables) were also obtained from all participants via a face-to-face interview by 3 investigators. The Body Mass Index (BMI) was calculated as weight (in kilograms) divided by the square of height (in meters) and classified according to WHO (World Health Organization) classification [26]. Underweight (<18.5), Normal (18.5-24.9), Overweight (25.0-29.9) and Obese (≥ 30.0) [26].

Two psychologists performed all the diagnostic assessments of symptoms and functioning using the Positive and Negative Syndrome Scale for schizophrenia (PANSS) [27], the Brief Cognitive Rating Scale (BCRS) [28] and the Morningside Rehabilitation Status Scale (MRSS) [29]. Briefly, the PANSS is used for measuring symptom severity in patients with schizophrenia and evaluating positive and negative symptoms of psychotic disorders [27]. The BCRS describes the severity of cognitive impairment providing five main axes (concentration, short term memory, long term memory, orientation, and self-care ability) and five co-axes (language, psychomotor, mood and behavior, drawing skills, calculating skills) each rated on a 7-step scale (1=no impairment; 7=most severe impairment) [28]. The MRSS scale is used to evaluate the level of general functioning in psychiatric patients. This scale allows the clinician to rate social adaptation of the subject on four axes: dependence/Independence, activity/inactivity level, the level of social integration/ isolation in addition to the effects

of present symptoms. Each axis is rated on a 7-step scale, with 0 meaning no disorder and 7 meaning an extreme degree of disability, with higher scores indicating greater dysfunction [29].

Vitamin D measurement blood samples and laboratory analysis

The laboratory analysis was performed at the Laboratory department of the PHC. 6ml of blood were drawn from the antecubital vein of each participant for the measurement of vitamin D. Vitamin D levels (serum 25-hydroxyvitamin D (25 OHD) were determined by chemiluminescence immunoassay (Architect I, Abbott Laboratories).

We divided the Vitamin D level in four groups to take into consideration participants with severe deficiency. These cut-offs were defined almost exclusively based on data from older populations and from western countries [30].

Statistical analysis

Statistical Package for the Social Sciences (SPSS) 22 was used for the data analysis. Student's t-test was used to compare continuous variables in two groups. Pearson correlation was used for linear correlation between continuous variables. For categorical variables, the χ^2 and Fisher exact tests were used. Multivariate analysis logistic regressions were carried out using variables that showed a p-value <0.2 in the bivariate analysis.

A backward logistic regression test was performed to identify the independent variables that affect 25(OH) D levels. Vitamin D variable categorized into two groups (Vitamin D<25nmol/l, Vitamin D>25nmol/l) [31,32] were used as dependent variables. Significance will be defined as a p-value less than 0.05 levels.

Results

Sociodemographic characteristics of the study sample

Overall 200 participants were enrolled. The mean age of schizophrenic patients was 37.00 ± 11.65 years compared to 38.77 ± 10.61 years for the controls (age ranging between 18 and 65 years for the whole sample). Most of the participants were male in each group (72% in control group, 70% in cases group). The majority of cases were single (76%), having an intermediate and below level of education (60%), and a low socioeconomic level (54%). On the other hand, 44% of the control group was single, 60% had secondary and high levels of education and the majority of them had an intermediate socio-economic level (76%). More than half of the patients were smokers (60%) versus 48% of the controls.

Most of the patients didn't have a history of medical illness (71%) and 42% of them had a family history of mental disorders, while all controls didn't have a family history of mental disorders 100% and almost all of them 88% didn't have a history of medical illness.

Almost half of the patients had normal BMI (48%), with 52% being overweight or obese, while most of the controls were overweight and obese (62%) and 38% having normal BMI.

A significant difference between the two groups was found for the geographic region, marital status, education level, socioeconomic level, history of medical illness, family history of psychiatric illness ($p < 0.005$).

Comparison of vitamin D category between schizophrenic patients and healthy control

Figure 1 shows the percentage of vitamin D level categorized according to IOM guideline between schizophrenic patients and healthy control. The results showed that 9% of schizophrenic patients had a severe vitamin D deficiency as compared to 3% in the control group. Almost half of the schizophrenic patients (49%) had vitamin D deficiency compared to 54% in healthy controls. Vitamin D insufficiency was found in 28% of schizophrenic patients compared to 37% in healthy controls, while vitamin D sufficiency was found in 14% of schizophrenic patients compared to 6% in healthy controls. The difference in vitamin D categories between controls and schizophrenics tended to significance ($p=0.053$).

Correlation between the severity of vitamin D deficiency in schizophrenic patients and schizophrenia symptoms, severity of cognitive impairment and the level of general functioning

Significantly higher BCRS and MRSS mean scores were found in schizophrenic patients with a more severe vitamin D deficiency ($p=0.006$ for both variables). However, we couldn't detect any significant difference between the total PANSS score and its three subscales with vitamin D level ($p>0.05$) (Table 1).

Bivariate analysis

Table 2 displays the bivariate analysis of the factors that might be correlated with severe vitamin D levels. Females had significantly more severe vitamin D levels than males ($p<0.001$). Having a family history of mental disorders and taking anticholinergic drugs were significantly associated with a more severe vitamin D deficiency

Table 2: Bivariate analysis for vitamin D divided into two categories.

		Vitamin D < 25 nmol/l	Vitamin D > 25 nmol/l	p-value
		Frequency (%)	Frequency (%)	
Gender	Male	14 (43.8%)	128 (76.2%)	<0.001
	Female	18 (56.3%)	40 (23.8%)	
Socioeconomic level	Low	14 (43.8%)	60 (35.7%)	0.124
	Intermediate	15 (46.9%)	103 (61.3%)	
	High	3 (9.4%)	5 (3.0%)	
Family History of Mental disorders	Yes	11 (34.4%)	31 (18.5%)	0.043
	No	21 (65.6%)	137 (81.5%)	
Anti-cholinergic drug	Yes	10 (43.5%)	16 (20.8%)	0.029
	No	13 (56.5%)	61 (79.2%)

	No	3 (33.3%)	36 (39.6%)	
Atypical antipsychotics drug	Yes	18 (78.3%)	53 (68.8%)	0.382
	No	5 (21.7%)	24 (31.2%)	
Anti-depressant drug	Yes	4 (17.4%)	10 (13.0%)	0.593
	No	19 (82.6%)	67 (87.0%)	
Mood stabilizers drug	Yes	11 (47.8%)	32 (41.6%)	0.594
	No	12 (52.2%)	45 (58.4%)	
Benzodiazepine drugs	Yes	5 (21.7%)	21 (27.3%)	0.595
	No	18 (78.3%)	56 (72.7%)	
Case-control group	Healthy Control	9 (28.1%)	91 (54.2%)	0.074
	Schizophrenic Patients	23 (71.9%)	77 (45.8%)	
		Mean ± SD	Mean ± SD	
	BCRS	19.06 ± 6.69	14.79 ± 5.24	0.006
	MRSS	16.44 ± 5.24	12.97 ± 4.33	0.006
	BMI	28.23 ± 7.48	26.22 ± 4.89	0.153
	Indoor activities	7.83 ± 15.57	15.38 ± 37.06	0.067
	Outdoors activities	12.00 ± 25.34	26.19 ± 53.59	0.026
	Sun exposure (in minutes)	37.67 ± 74.96	67.41 ± 68.74	0.033

($p=0.043$ and $p=0.029$) respectively. Higher BCRS and MRSS mean scores were significantly associated with more severe vitamin D deficiency ($p=0.006$ for both). An increased mean time of outdoor activities and sun exposure were significantly associated with a higher level of vitamin D ($p=0.033$ and $p=0.026$) respectively. No significant difference was found between typical antipsychotics, atypical antipsychotics, antidepressants, mood stabilizers, benzodiazepines, and socioeconomic level, BMI and the two categories of vitamin D ($p>0.05$).

Multivariable analysis

A backward logistic regression, using the two-category vitamin D level as dependent variable, showed that intermediate and high socioeconomic level would significantly increase the odds of having an increased level of vitamin D as compared to low socioeconomic level by 54.5% and 34.1% respectively (OR= 141.919, CI 1.545 - 13036.060, $p = 0.032$ and OR= 132.110, CI 1.341 - 13016.132, $p = 0.037$ respectively). Sun exposure would significantly increase the

Table 3: Multivariable analysis.

Logistic regression taking vitamin D divided into two categories (<25 nmol/l and >25 nmol/l) as dependent variable				
	OR	95% C.I		p-value
Sun exposure	1.046	1.007	1.086	0.022
MRSS	0.848	0.731	0.984	0.029
Socioeconomic level				0.099
Intermediate socioeconomic level	141.919	1.545	13036.06	0.032
High socioeconomic level	132.11	1.341	13016.132	0.037

odds of having an increased vitamin D level by 4.6% (OR= 1.046, CI 1.007- 1.086, p = 0.022). Furthermore, higher MRSS scores would significantly increase the odds of having a more severe vitamin D deficiency by 15.2% (OR= 0.848, CI 0.731 – 0.984, p =0.029) (Table 3).

Discussion

To our knowledge, this is the first study that investigates the level of vitamin D in Lebanese schizophrenic patients. Our results showed that patients with schizophrenia, compared to healthy controls, had similar vitamin D levels, although severe deficiency in vitamin D levels were demonstrated three times more in the patients. This could be due to insufficient sample size or the existence of vitamin D deficiency in controls.

The desirable vitamin D levels, and thus hypovitaminosis D, have been set using international guideline based cut-offs and lately have been a matter of great debate. The Endocrine Society guidelines in 2011 [33] had set a cut-off point at 30ng/mL (75nmol/L) while the Institute of Medicine Report (IOM) had set a cut off at 20ng/mL (50nmol/L) in 2011 [34]. According to the IOM guidelines vitamin D levels are categorized into deficient (below 50nmol/L), insufficient (50-75 nmol/L) and sufficient (more than 75nmol/L) [34,35]. A level below 25nmol/l (10ng/ml) was considered as severe deficiency [31,32]. A meta-analysis, including 19 studies (2804 participants), showed a strong association between vitamin D deficiency and schizophrenia [2], with 65% of them being vitamin D deficient [2]. Other studies [6,36,37] showed that adults with schizophrenia have significantly lower serum concentrations of vitamin D as compared with healthy controls. It was expected that vitamin D levels in the Lebanese population would be higher due to the sunny climate. In fact, Lebanon is located at appropriate latitudes (33° 35'N) [38] for the synthesis of vitamin D [39] and thus, higher levels of total vitamin D would be expected [39]. Furthermore, our results indicated that patients with schizophrenia, as well as the healthy ones, had a vitamin D deficiency, similar to previous studies [2,4,36,37,40,41]. Other studies conducted in Lebanon had shown a hypovitaminosis D in the healthy population [35,42-45].

Schizophrenic patients are on a wide variety of medications, including anticonvulsants and antipsychotic drugs [46,47]. Our findings showed no significant association between those taking antipsychotics and vitamin D level, in line with other studies that showed no effect of antipsychotics on vitamin D level [1,48,49]. It is hypothesized that anti psychotics would cause hypogonadism and might predispose the patient to a higher risk of osteoporosis [50] however, it is not known whether there are direct effects of this class of medications on vitamin D status [1]. Some anticonvulsant

medications might increase the rate of vitamin D removal from the body via the liver [51] by enhancing the catabolism of vitamin D [47], thus, putting the patient at risk of low vitamin D levels.

Vitamin D deficiency may be due to cultural requirements that limit sun exposure, as well as to low vitamin D intake [35]. In addition, big cities have a higher degree of air pollution that contains ozone, thus leading to an efficient atmospheric absorption of UVB photons, thereby reducing the skin photosynthesis of vitamin D52. Unfortunately, Beirut is actually a much polluted city, with no continuous measurement of its pollution level [43].

We recorded an inverse association between vitamin D level MRSS and BCRS scales respectively. No study has evaluated the association between MRSS, BCRS and hypovitaminosis D in schizophrenic patients. Increasing the behavioral and cognitive function would increase outdoor activities and exposure to sunlight [1,48]. Different studies had reported that insufficiency or deficiency of vitamin D is associated with cognitive impairment [1,23,53-56]. Vitamin D deficiency can be associated with muscle weakness that might lead to cognitive impairment [57]. Furthermore, our schizophrenic patients had a sedentary lifestyle, including social isolation and lack of motivation, leading to poorer nutrition and less time spent outdoors that would contribute to lower vitamin D levels [58].

Our findings did not show a significant association between vitamin D levels and schizophrenia symptoms, in opposite to the study of Graham et al. [1] which was the first to report an association of vitamin D insufficiency with more severe negative symptoms and poorer neurocognitive function in patients with schizophrenia. This can be due to the fact that our patients were still in early adulthood, confirming the fact that low vitamin D status in late adolescence or early adulthood is unlikely to be causally related to schizophrenia risk in these subjects 1. These results need to be confirmed by future studies.

Our results showed that sun exposure and the socioeconomic level was significantly associated with increased vitamin D level. We observed that the number of weekly reported hours of sun exposure was positively correlated with an increased level of vitamin D. Eyles et al. [3] suggested that lower exposure to sunlight, which is required for the production of vitamin D, is associated with higher schizophrenia risk. Another study done by Itzhaky et al [36] did not find a significant difference between daily sun exposure and schizophrenia. Our finding reinforces the importance of sun exposure as a source of vitamin D. This study was done during spring and summer season where sun exposure is appropriate for the synthesis of vitamin D. Season affect vitamin D synthesis in the skin [35]. Lower serum 25-hydroxyvitamin

D levels are reported in winter and spring compared to summer and fall in studies from temperate regions in the developing world [35].

Our results showed that intermediate and high Socioeconomic Status (SES) was associated with increased level of vitamin D, similar to a study done by Arabi et al [35] which reported that individuals with hypovitaminosis D were mostly of low socioeconomic status. However, previous studies [9,59] did not show a relation between vitamin D and SES. Families with low SES had restricted access to the nutritional variety and food quality (food cost is an important factor affecting food choice) and have low activities lifestyles (low income could discourage outdoor activities) [60,61].

Limitations

There are several limitations of this study. It's a single center study, thus does not reflect vitamin D statuses among all hospitalized schizophrenic patients. The sample size for this study remains small, with additional larger studies needed to confirm our findings. The season during which this study was conducted might have influenced our results. Further prospective studies should take this limitation into account. An information bias is possible since the evaluation of lifestyle activities, including diet, outdoor activity, and daily sun exposure was done through a direct interview and is subjective. The information collected directly from patients could have been affected by the low level of cognition due to the negative effect of antipsychotics treatment. In addition, we did not screen specifically for malabsorption problems in both schizophrenics and control groups, which might confer a higher risk of vitamin D deficiency.

Conclusion

Vitamin D insufficiency is prevalent in patients with schizophrenia. Further work is needed to answer the question of causality. Does vitamin D deficiency play a vital role in the pathogenesis of schizophrenia? The theory of a genetic interaction between schizophrenia and vitamin D is possible. Future cohort studies may investigate the association with longer follow-up.

In the meantime, it is important that health care professionals be aware of the high rates of vitamin D deficiency among schizophrenics. Spreading awareness among health care professionals for routine serum vitamin D testing, along with patient education, are necessary to avoid this problem.
