Abstract

Superficial endometriosis involving the serosa of the colon is not an uncommon presentation. However, Deep Infiltrating Endometriosis (DIE) involving more than 5mm of the peritoneal surface reaching up to the muscularis propria and submucosa is rare. Further DIE causing luminal stricture and colonic obstruction occurs in less than 1.7% of the cases. We report a case of a forty six year old woman who initially presented for evaluation of cyclical abdominal pain. Radiologic and endoscopic investigations were suggestive of a malignancy. She underwent surgery including laparoscopic low anterior resection of sigmoid colon with side-to-end coloproctostomy and bilateral salpingo-oophorectomy. The histopathology revealed multiple endometriotic implants involving the submucosa, muscularis propria and serosa of the sigmoid colon. A left ovarian endometrioma was also identified. Our case highlights the diagnostic challenge in establishing an accurate pre-operative diagnosis and differentiates DIE from colon cancer. A multidisciplinary team approach with a combination of medical and surgical interventions can achieve effective therapy.

Keywords: Deep infiltrating endometriosis; Colon cancer

Case Presentation

A forty six year old gravida two Caucasian female with medical history of essential hypertension presented to our clinic for the management of abdominal pain for five months. She underwent a laparoscopic assisted vaginal hysterectomy, for pain and irregular bleeding, eight months prior to initial presentation. The pathology from the hysterectomy specimen showed benign endometrium with adenomyosis. Postoperatively, she experienced cyclical pain every 28 days, moderate in intensity and localized to the left lower quadrant of the abdomen. There was no history of dyspareunia, dyschezia, hematochezia or hematuria. She denied any weight loss or fever. Her physical examination was unremarkable except for a BMI of 31.7kg/m². A left sided pelvic mass was seen on CT abdomen and pelvis. CT colonography revealed an apple core lesion measuring 3.3cm in the mid-sigmoid region with severe stenosis of the lumen, suggestive of malignancy (Figure 1). Colonoscopy demonstrated a severe stenosis 25cm above the anal verge. Biopsies were inconclusive with nonspecific reactive changes of the colonic mucosa. Her serum CEA level was 0.6.

The presumptive clinical diagnosis was colonic malignancy. However, due to symptoms of cyclical pain a differential diagnosis of colonic endometriosis was also considered. The patient underwent bilateral ureteral stenting with laparoscopic low anterior resection of the sigmoid colon with side-to-end coloproctostomy at 12cm above the anal verge. Bilateral salpingo-oophorectomy was also performed. Intraoperatively, numerous endometriotic deposits and adhesions were noted in the pelvis. The left ovary was markedly enlarged and filled with chocolate colored fluid, consistent with an endometrioma. The right tube and ovary appeared normal. A purplish mass was seen on the sigmoid colon suggestive of endometriosis.

On gross examination, a 3.5cm x 2.5cm dark red puckered, indurated luminal stricture measuring 4.0cm in circumference was noted in the resected sigmoid colon specimen. The wall of the stricture area measured 1.5cm in thickness (Figure 2). The histopathology revealed multiple endometriotic implants involving the submucosa, muscularis propria and serosa. There was no evidence of malignancy (Figure 3a, 3b). Left ovary measured 3.4cm x 3.0cm x 1.7cm with a 2.4cm unilocular ovarian endometrioma. Left fallopian tube, right ovary and fallopian tube were unremarkable. A final diagnosis of deep infiltrating sigmoid endometriosis was made. Postoperatively, the patient recovered well and has been symptom free for 18 months. She was started on estrogen replacement therapy for postmenopausal symptom relief without complications.

Discussion

Endometriosis is a progressive and benign estrogen-dependent disease defined by the presence of endometrial tissue (glands and stroma) outside the uterine cavity. First described in 1860 by Von

Figure 1: Pre-operative CT colonography shows "apple core" lesion within mid-sigmoid, measuring 3.3cm with severe stenosis of the lumen. Diverticulosis of the sigmoid seen. No extra colonic findings.

Figure 2: Resected sigmoid colon with central maroon puckered indurated area, hemorrhagic serosal implants and serosal adhesions.

Rokitansky, it is present in up to 10% of women in reproductive age group [1]. Extra pelvic endometriosis is seen in 3.8% to 37% of all cases [2]. In 5.3% to 12% of these women, endometriosis involves the bowel [3].

The recto-sigmoidal junction is the most common site involved (65.7%) followed by sigmoid colon (17.4%). Cecum with the ileocecal junction (4.1%), appendix (6.4%), small bowel (4.7%) and omentum (1.7%) are the other sites described [4].

Various theories proposed in the pathogenesis of endometriosis indicate that the etiology is complex and multifactorial, involving retrograde menstruation, lymphatic dissemination, immune dysfunction and coelomic metaplasia. The endometrium and peritoneal mesothelium being derivatives of the same coelomic wall epithelium explains the latter theory. Iatrogenic deposition of endometrial tissue following gynecologic procedures and caesarean sections may also explain occurrence of colonic endometriosis. In the current case, the patient underwent laparoscopic hysterectomy eleven months prior to the diagnosis of DIE [5].

Colonic involvement could either be superficial or deep (DIE). The latter, also known as adenomyosis externa, is defined as endometriosis located more than 5mm beneath the peritoneal surface [6]. Several classification systems have been attempted to explain the phenotypes of DIE based on the depth of invasion as well as anatomical site of the deposits [7-9].

The symptoms of intestinal endometriosis vary according to the site of involvement. The common symptoms are rectal bleeding and pain, altered bowel habits, abdominal bloating and cramping, most of which tend to get worse during menstruation [10]. However, DIE presenting as luminal stenosis and colonic obstruction is rare (1.7%) [11]. The lack of pathognomonic signs makes the diagnosis difficult. This often leads to a pre-operative diagnostic challenge to differentiate intestinal endometriosis from malignant tumors, inflammatory bowel disease or ischemic colitis.

The optimal manner for identification of intestinal endometriosis is by direct visualization of the implants at surgery. Radiologic and endoscopic examinations, though not diagnostic, are essential preoperative evaluations. Computerized Tomography (CT) colonography and Magnetic Resonance Imaging (MRI) are highly sensitive tests for the detection of DIE, the former having a higher overall diagnostic accuracy (area under the curve, 0.786 vs 0.691; $P < 0.001$). Changes in lumen caliber with bowel wall thickening

Figure 3a: Serosal endometriotic glands and stroma implants (bottom center) with multiple deep muscularis propria endometriosis foci. There is surrounding hyperplastic smooth muscle and serosal fibrosis (H&E, original magnification X20).

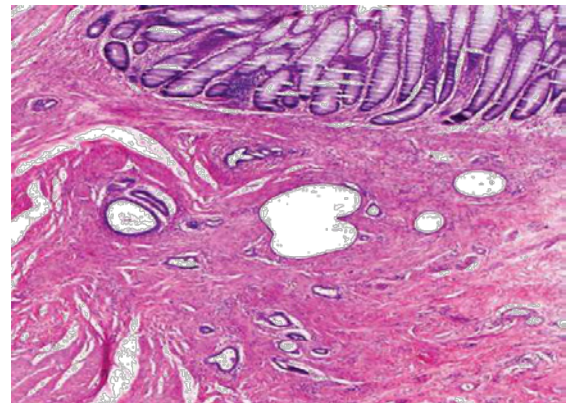

Figure 3b: Unremarkable colonic mucosa (top) overlying endometriotic foci within the submucosa and muscularis with resultant submucosal expansion and muscularis hypertrophy (H&E, original magnification x 100).

and mass formation have been shown to significantly correlate with morphologic changes in rectosigmoid endometriosis [12]. Colonoscopy usually reveals an eccentric wall thickening, luminal stricture with or without surface nodularity. A biopsy of a suspicious lesion may be done. However histologic diagnostic yield could be as low as 47% since DIE is usually limited to the serosa or muscularis propria and the biopsy specimen usually consists of mucosal tissue [13]. Recto-sigmoid endoscopic-ultrasound has recently been shown to have comparable sensitivity to MRI for evaluation of rectal and sigmoid infiltrates and depth of infiltration [14,15].

To achieve the best therapeutic result, a multidisciplinary treatment team consisting of a gynecologist, colorectal surgeon and urologist, is ideal. The choice of the surgical intervention depends on the site and depth of bowel infiltration. It can range from shaving (superficial peeling of serosa with laser or diathermy), to superficial excision (selective removal of implants without entering the bowel mucosa). More deep involvement of muscularis propria, submucosa and mucosa are treated by full thickness disc excision (excision of the implants with opening, followed by closure of the bowel wall) or bowel resection and anastomosis [16]. Minimally invasive treatment options are favored over open surgery, enhancing recovery and patient outcome.

Adjuvant therapy has been proven to decrease mean pain scores

and lesion size with improved quality of life [17]. Combination regimen with progestin is more accepted and better tolerated than GnRH analogues. Women who underwent radical surgical treatment for severe endometriosis had significantly increased median time to symptom recurrence with a combination of aromatase inhibitors with either a progestin or gonadotropin-releasing hormone (GnRH) analogue [18].

Conclusion

Deep infiltrating endometriosis of the colon benefits from a multidisciplinary treatment approach. Aggressive surgical and medical management is recommended for optimal resolution of symptoms. DIE should be considered in the differential diagnosis of presumed malignant colonic strictures in a premenopausal woman with cyclical gastrointestinal symptoms.
