Neurodegenerative diseases are unrelenting, unforgiving and cruel given the long duration of patient suffering due to the impact of progressive damage within specific brain locations. In the case of dementias, there is a direct impact on memory and cognitive processing, and the loss of personal dignity and worth. Ultimately, the patient loses the ability to maintain basic hygiene placing attentional responsibilities on family members and support staff. With respect to neurodegenerative diseases of the eye, the patient must deal with progressive deleterious changes in vision resulting from retinal damage. This review discusses the role of the Renin-Angiotensin System (RAS) in cardiovascular disease, Alzheimer's and Parkinson's diseases, Type 2-induced dementia, depression, glaucoma, macular degeneration and diabetic retinopathy. We conclude with a consideration of the challenges posed regarding the development of new drugs designed to treat dementias, depression, and neurodegenerative diseases of the eye. The use of small molecule agonist and antagonist analogs of RAS components is discussed. These analogs can be configured to pass the blood-brain barrier and target relevant receptor proteins in specific brain structures or they can be applied topically to the eye to discourage increases in intraocular pressure, decreased retinal microvascular blood flow, tissue inflammation and oxidative stress as well as the accumulation of extracellular material (drusen) that can disrupt normal vision. Along with suggested drug development strategies, several important drug targets are identified in an effort to focus attention, and facilitate research efforts, to improve drug efficacy and thus provide better clinical outcomes for these patients.

Keywords: Renin-angiotensin system; Angiotensin receptors; Angiotensin receptor blockers; Dementias; Glaucoma; Macular degeneration

Abbreviations

A β : Amyloid-Beta Peptide; ACE: Angiotensin Converting Enzyme; ACEi: Angiotensin Converting Enzyme Inhibitor; AD: Alzheimer's Disease; AH: Aqueous Humor; AMD: Age-Related Macular Degeneration; AP: Area Postrema; APA: Aminopeptidase A; APN: Aminopeptidase N; AngII: Angiotensin II; AngIII: Angiotensin III; AngIV: Angiotensin IV; ARB: Angiotensin Receptor Blocker; AT₁: Angiotensin Receptor 1; AT₂: Angiotensin Receptor 2; BBB: Blood-Brain Barrier; BDNF: Brain-Derived Neurotrophic Factor; Carb-P: Carboxypeptidase P; CBF: Cerebral Blood Flow; CVOs: Circumventricular Organs; DA: Dopaminergic; DR: Diabetic Retinopathy; HGF: Hepatocyte Growth Factor; IGF-1: Insulin-Like Growth Factor; IOP: Intra-Ocular Pressure; IRAP: Insulin-Regulated Aminopeptidase; L-DOPA: Levodopa; LTP: Long-Term Potentiation; Mas: MAS1 Oncogene; MCI: Mild Cognitive Impairment; Met: N-Methyl-N'-Nitro-N-Nitrosoguanidine; MDD: Major Depressive Disorder; MPP+: MPTP Metabolite; MPTP: 1-Methyl-4-Phenyl-1,2,3,6-Tetrahydropyridine; MRI: Magnetic Resonance Imaging; NGF: Nerve Growth Factor; NADPH: Nicotinamide Adenine Dinucleotide Phosphate; NO: Nitric Oxide; NTS: Nucleus of the Solitary Tract; PD: Parkinson's Disease; PAI-1: Plasminogen Activator Inhibitor 1; PO: Propyl Oligopeptidase; RAS: Renin-Angiotensin System; RPE: Retinal Pigment Epithelial Complex; SFO: Subfornical Organ; T2D:

Type 2 Diabetes; VEGF: Vascular Endothelial Growth Factor

Introduction

The Renin-Angiotensin System (RAS) is recognized as one of the oldest hormone systems best known for its roles in regulating blood pressure and body water balance. In 1891 Robert Tiegerstedt and his student Per Bergan identified a pressor agent extracted from rabbit kidney tissues that they called "renin" [1]. Fifty years later, this finding led to the discovery of a vasoconstrictor agent isolated from ischemic kidneys of Goldblatt hypertensive dogs [2]. Page and Helmer [3] independently found the same molecule after injecting renin into intact animals. They also identified a "renin activator" later reported to be angiotensinogen [4]. This vasoconstrictor agent was eventually determined to be an octapeptide variously called, "renin substrate", "hypertension" and "angiotensin", ultimately termed Angiotensin II (AngII) [5-7].

This review initially describes the presently identified angiotensin ligands and their respective receptor subtypes. Angiotensin 1 and 2 (AT₁ and AT₂) subtypes have been well characterized and the AngII/AT₁ system is particularly important in the etiology of cardiovascular diseases [4,8,9]. The AT₃ subtype was first isolated in mouse neuroblastoma cell cultures [10,11], but a separate gene has thus far not been sequenced in humans. The identity of the AT₄ subtype has

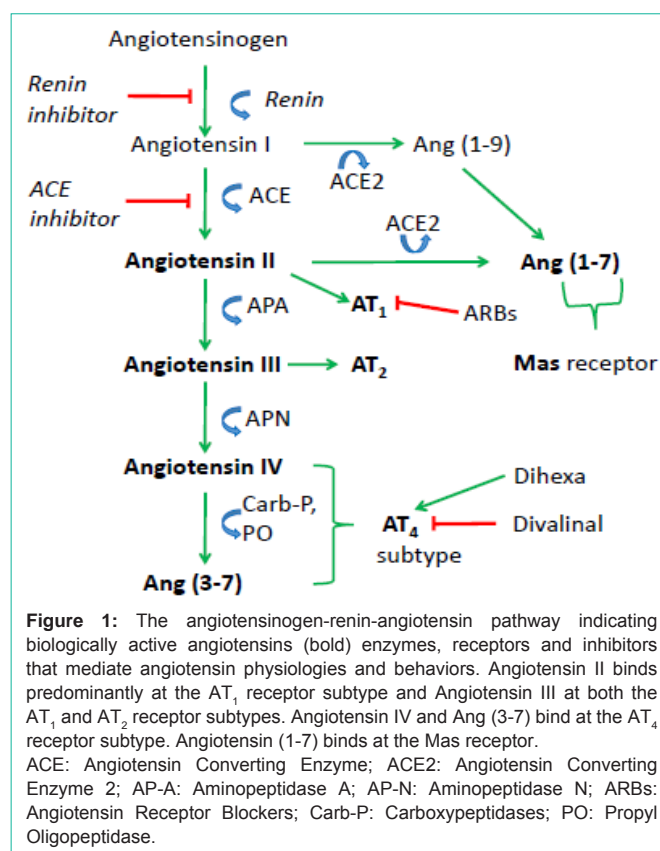

been controversial and will be discussed. Next, we will focus on the role of the brain Ang IV/AT₄ receptor system in several neurodegenerative diseases. Additional diseases of the eye are identified as important targets requiring much additional research attention regarding the RAS and its relevance. Finally, recommendations are offered concerning drug development approaches in order to penetrate the blood-brain barrier and influence the brain RAS. Target diseases include dementias associated with Alzheimer's and Parkinson's diseases, Type II diabetes, as well as depression/neuroinflammation and diseases impacting the retina of the eye.

The Renin-Angiotensin System

The RAS is responsible for mediating several classic physiologies such as the regulation of systemic blood pressure and body water/electrolyte balance, as well as a number of novel physiologies and behaviors including influences on sexual reproduction and behavior, Cerebral Blood Flow (CBF) and cerebroprotection, seizures, stress, depression, and memory [12,13]. AngII binds at the G-protein coupled AT₁ receptor subtype [14-16]. Over the years the AngII/AT₁ receptor system has been a major focus regarding the development of antihypertensive drugs and its role in promoting inflammation, oxidative stress and tissue remodeling [17,18]. These processes contribute to the "neuronal inflammation response" a key factor in the development of neurodegenerative diseases including Alzheimer's Disease (AD) [19-21]. The biologically active angiotensin peptides are derived from the protein angiotensinogen (255 amino acids) via a cascade of enzymatic activity and include AngII (Asp-Arg-Val-Tyr-Ile-His-Pro-Phe), AngIII (Arg-Val-Tyr-Ile-His-Pro-Phe), Angiotensin IV (AngIV: Val-Tyr-Ile-His-Pro-Phe), Ang (1-7) (Asp-Arg-Val-Tyr-Ile-His-Pro) and Ang (3-7) (Val-Tyr-Ile-His-Pro) (Figure 1) [22-25]. Specifically, the decapeptide angiotensin I (AngI: Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His-Leu) is formed by renin (EC 3.4.23.15) acting upon the N-terminal of angiotensinogen. AngI serves as a substrate for angiotensin Converting Enzyme (EC 3.4.15.1) which is responsible for hydrolyzing the carboxy terminal dipeptide His-Leu to form AngII. AngII is converted to the heptapeptide AngIII by glutamyl aminopeptidase A (APA; EC 3.4.11.7) cleavage of the Asp residue at the N-terminal [26-28]. AngIII is acted upon by membrane alanyl aminopeptidase N (APN; EC 3.4.11.2) resulting in the cleavage of Arg to form the hexapeptide AngIV. AngIV can be further converted to Ang (3-7) by Carboxypeptidase P (Carb-P) and Propyl Oligopeptidase (PO) cleavage of the Pro-Phe bond. Angiotensin (1-7) is formed from AngII via Carb-P cleavage of Phe [29], by the mono-peptidase ACE2 [30,31], and by ACE cleavage of the dipeptide Phe-His from Ang (1-9) [32].

Ang II/AT₁ and AngIII/AT₂ receptor systems

The AT₁ receptor subtype belongs to the superfamily of 7-transmembrane domain receptors and the AT₁ gene is located in chromosome 3q and codes for a 359 amino acid protein (40-42 kDa) [14-16]. Signaling by the AT₁ receptor is via phospholipase-C, -A₂, -D-adenylate and calcium (L- and T-type voltage sensitive channels) [4,33,34]. The AT₁ receptor is also coupled to intracellular signaling cascades involved in the regulation of gene transcription and protein expression that mediate cellular proliferation and growth in a number of target tissues, both peripheral and central. The AngII/AT₁ receptor system is a major player in cardiovascular functioning

via direct inotropic influences on the heart and increases in vascular resistance [22,35]. Increased vascular resistance occurs due to direct vasoconstriction of vascular smooth muscle and indirect action via the brain resulting in sympathetic nervous system arousal, the inhibition of the baroreceptor reflex, and the release of the powerful vasoconstrictor arginine-vasopressin [36-38].

The AT₂ receptor subtype is also a 7-transmembrane domain G-protein coupled receptor; however, it exhibits only about 32-34% amino acid sequence identity with the AT₁ receptor [39,40]. This protein consists of a 363 amino acid sequence (40-41 kDa) [41] and is sensitive to AngII, but exhibits a higher affinity for AngIII [42]. This receptor is expressed in developing fetal tissues but decreases after birth and remains at low levels in adult tissues. The AT₂ receptor subtype appears to modulate cell proliferation, cell differentiation, apoptosis, and regenerative processes and generally opposes actions initiated by the AngII/AT₁ system [43,44]. It is important to note that the AT₂ receptor can be upregulated during pathological conditions [45,46], although it is not clear to what extent this occurs in patients with neurodegenerative diseases.

Angiotensin IV/AT₄ receptor system

Some time ago our laboratory, and others, discovered a binding site with nanomolar affinity for AngIV using bovine adrenal cortex membranes [47-49] and guinea pig hippocampal tissues [50]. The pharmacological profile of this receptor was shown to be distinct from the AT₁ and AT₂ subtypes. It was also determined that (¹²⁵I)-AngIV binds at the AT₄ site reversibly, saturably, and with high affinity. Binding was found to be insensitive to guanine nucleotides,

indicating that this receptor protein is not G-protein-linked. Further, the AT₄ receptor evidenced as a dimer, as seen in growth factors, with a molecular weight of 160-190 kDa as determined by reduced SDS-polyacrylamide gel electrophoresis [51]. This subtype is distributed within a number of brain structures with heavy concentrations in the hippocampus, nucleus basalis of Meynert, piriform cortex and neocortex, structures concerned with the mediation of cognition, learning and memory [52].

The AT₄ receptor subtype has a positive influence on a number of physiological and behavioral functions including CBF, neuroprotection, synaptogenesis, Long-Term Potentiation (LTP), and memory consolidation and retrieval [53,54]. Jan Braszko and colleagues [55-57] were the first to report that intracerebroventricular injected AngIV facilitated exploratory behavior in rats tested in an open field, improved recall of passive avoidance conditioning and the memory acquisition of active avoidance conditioning. Members of our laboratory confirmed these memory results and further reported AngIV-induced dose dependent increases in CBF without significant changes in systemic blood pressure [58,59]. These effects could not be blocked by AT₁ or AT₂ receptor antagonists, but were prevented by pretreatment with the AT₄ receptor antagonist divalinal-AngIV. Related to this, Naveri and colleagues [60] have shown that AngIV infusion restored CBF following subarachnoid hemorrhage. Further, Dalmy et al. [61] reported that AngIV infusion following pretreatment with the AT₁ receptor blocker candesartan slightly decreased mortality at post-surgery Day 3 in the gerbil model of unilateral carotid artery ligation, but significantly decreased lisinopril-induced mortality. These results support the hypothesis that the activation of AT₄ receptors contributes to cerebroprotection. This neuroprotective role for the AT₄ receptor subtype is consistent with the notion that AngIV increases blood flow by a Nitric Oxide (NO)-dependent mechanism [59]. In agreement with this hypothesis Faure et al. [62] has shown that internal carotid artery administration of increasing doses of AngIV significantly decreased mortality and cerebral infarct size in rats 24 hours following embolic stroke due to the intracarotid injection of calibrated microspheres. Pretreatment with the AT₄ receptor antagonist divalinal abolished this protective effect. Sequential cerebral arteriography indicated that AngIV caused the redistribution of blood flow to ischemic areas within a few minutes. It is hypothesized that AngIV may yield its neuroprotective effect against acute cerebral ischemia via an intracerebro-hemodynamic AT₄ receptor-mediated NO-dependent mechanism. Most recently we have noted an interaction between AngIV-based analogs and the Hepatocyte Growth Factor (HGF)/Met system with evidence suggesting that the AngIV/AT₄ receptor system coincides with the HGF/Met receptor system [54].

A potentially important advance in our understanding of the RAS was the finding that AngIV's actions may be mediated in part by insulin-regulated aminopeptidase (IRAP: EC 3.4.11.3) and the hypothesis that this enzyme is the AT₄ receptor [63,64]. IRAP is a Type 2 transmembrane protein of the gluzincin aminopeptidase family which includes homologous aminopeptidases such as aminopeptidases A and N [52,65]. IRAP co-distributes with the GLUT4 transporter [66,67]. The key substrates acted upon by this enzyme appear to be arginine-vasopressin and oxytocin [68]. It is proposed that the physiological and behavioral actions of AngIV are

due to competitive inhibition of IRAP's peptidase activity resulting in an extended half-life of AngIV and particularly oxytocin and vasopressin. IRAP has the capacity to cleave N-terminal amino acids from a number of peptides including met-enkephalin, dynorphin, oxytocin, arginine-vasopressin, lysine-bradykinin, neurokinin A1, somatostatin, neuromedin B, and cholecystokinin-8. IRAP has been variously identified as oxytocinase, cysteine aminopeptidase, placental leucine aminopeptidase, gp160, or vp165 [69]. Thus, IRAP inhibition by Ang IV results in the potentiation of several pro-cognitive endogenous peptides including arginine-vasopressin, oxytocin, somatostatin and cholecystokinin-8 [70]. However, Albiston and colleagues [68] reported that IRAP gene knock-out mice revealed impaired performance on memory tasks rather than enhanced performance as predicted. This finding casts some doubt concerning the relative importance of IRAP's role in the potentiation of memory formation and retrieval. In a subsequent report, these investigators measured an absence of IRAP in members of a postnatal forebrain neuron-specific IRAP knockout mouse line. As predicted these animals' revealed dysfunctions in spatial and object recognition memory at three months of age. The results suggested that the presence of IRAP in the postnatal brain may be necessary for normal memory functioning [71].

Members of our laboratory have questioned the notion that IRAP is the AT₄ receptor [42] and offered another possibility, namely the Hepatocyte Growth Factor (HGF)/Met receptor system [12,52,72-76]. This came about based on a search for a molecular target with a chemical structure similar to AngIV, and behavioral and physiological functions in agreement with those discovered for the AngIV/AT₄ receptor system. A partial match was seen with the protein angiostatin, and a related member of the plasminogen family HGF. Functions associated with the HGF/Met system overlap with those mediated by the AngIV/AT₄ system including facilitated memory consolidation, augmented neurite outgrowth, hippocampal LTP and calcium signaling, dendritic arborization, facilitation of CBF and cerebroprotection, seizure protection, and facilitated wound healing [52,53,74]. This prompted the hypothesis that AngIV and AngIV analogs may function via the HGF/Met system. We have reported that the AT₄ receptor antagonist Norleual-AngIV inhibited HGF binding to Met and HGF-dependent signaling, proliferation, invasion, and scattering [72]. Norleual-AngIV's mechanism of action regarding this ability to act as a Met receptor antagonist is by inhibiting the dimerization of HGF which serves as a prerequisite to Met receptor activation [72,77]. HGF dimerization is a necessary step in order to bind to and activate the Met receptor [78,79]. This dimerization process is dependent upon a short HGF domain located between its N-terminal and first Kringle domain referred to as the "hinge region" (Figure 2) [13,79]. Members of our laboratory have shown that a hexapeptide, designed to mimic the hinge region, bound to HGF with high affinity and blocked HGF dimerization [77]. We hypothesized that AngIV and AngIV analogs bind at this hinge region and facilitate HGF activation thus leading to increased Met receptor activation. There is now evidence that this appears to be the case [80].

Clearly it is not necessary that this issue be resolved in favor of one hypothesis or the other, since it has been shown that AngIV and AngIV analogs interact with both IRAP [65] and the HGF/Met system [13]. It is likely that these systems work together such that

competitive inhibition of IRAP functions to extend the half-life of AngIV allowing it a longer duration to bind at the HGF/Met receptor system. In addition, as mentioned earlier AngIV can be converted to Ang (3-7) which also binds at the AT₄ receptor. This friendly controversy concerning the identity of the AT₄ receptor, plus new important findings about the Ang (1-7)/Mas receptor system, has served to reinvigorate research interest in the brain RAS. Members of our respective research groups have cooperated on past projects [81] and hopefully this collaboration can continue in the future.

Angiotensin (1-7)/mas receptor system

Ang (1-7) binds at the Mas receptor that is also G-protein-coupled and has been shown to counteract peripheral organ inflammation and fibrosis, increase glucose utilization, and decrease insulin resistance [82-84]. The Mas receptor is present in brain structures associated with memory and cognition including hippocampal and piriform cortices [85]. Consistent with these observations Ang (1-7) has been shown to facilitate LTP (a presumed building block of memory formation) in the CA1 region of the hippocampus via activation of the Mas receptor [82]. The reader is referred to the following articles and reviews concerned with detailed characterization of the angiotensin receptor subtypes, and the Mas receptor [4,31,52,83,86,87].

Independent brain RAS

During the 1970s Detlef Ganten and colleagues reported the presence of renin and AngII in the dog brain resulting in the

recognition of an intrinsic independent brain RAS [88-90]. This amazing discovery, along with subsequent research findings, revealed that the brain RAS is one of many local RASs that mediate intracellular communication among various cell types (a paracrine role) as well as same cell types (an autocrine role) [91,92]. These local systems, for example the heart, liver, intestine, pancreas, ovary, uterus, testis, and eye cooperate in the regulation of cell differentiation, growth, proliferation, metabolism, apoptosis, tissue inflammation, fibrosis, hemodynamics and hormone secretion [93-95]. Following Ganten's discovery other investigators reported that intracerebroventricular injections of AngII in animal models produced potent increases in blood pressure via activation of AT₁ receptors located in Circumventricular Organs (CVOs), particularly the Subfornical Organ (SFO) and Area Postrema (AP), that project to the paraventricular and supraoptic nuclei of the hypothalamus [37,96]. Microinjections of AngII into the SFO and organum vasculosum of the lamina terminalis also elicited reliable elevations in blood pressure [97,98]. The pressor response due to circulating AngII was shown to be mediated primarily by the SFO and AP. The absence of a Blood-Brain Barrier (BBB) at these CVO sites permits penetration by this peptide and other circulating hormones. AngII also activates cardiovascular centers in the medulla. Target structures include the Nucleus of the Solitary Tract (NTS), AP and anterior ventrolateral medulla [38]. In particular, the AP detects blood-borne AngII as does the NTS which influences the baroreceptor reflex [99,100]. AngII delivered to the anterior ventrolateral medulla increases blood pressure by facilitating the sympathetic nervous system and catecholamine release from the adrenal medulla [100,101-103]. In summary, an overactive RAS can result in a hypertensive state accompanied by reduced cerebral blood flow, elevated oxidative stress and a pro-inflammatory response, resulting in cognitive dysfunction [13].

Cardiovascular Disease

Nearly fifty years ago it was reported that minor structural modifications of AngII yielded peptides capable of acting as antagonists at the AT₁ receptor subtype. Two of these compounds, saralasin (Sar1, Ala8-AngII) and sarile (Sar1, Ile8-AngII) were evaluated in clinical trials but were dismissed primarily because of their peptidic structures [104-107]. Even so these peptides have been useful as research tools that highlighted the importance of the RAS, and particularly the AT₁ receptor, in mediating systemic blood pressure [65]. Such studies led to the development of the first non-peptidic Angiotensin Receptor Blocker (ARB) losartan, in 1995 [108]. Since then, several additional ARBs have been introduced and successfully taken through clinical trials including candesartan eprosaran, olmesartan, telmisartan and valsartan [109,110]. Azilsartan is the most recent to receive FDA approval in 2011 [111]. All are antihypertensive drugs designed to block the AT₁ receptor subtype and reduce blood pressure. In addition, both losartan and candesartan have been shown to facilitate cognitive processing in elderly hypertensive patients, an important observation [112-115].

The zinc-binding thiol compound captopril was the first Angiotensin-Converting Enzyme Inhibitor (ACEi) to be developed as an anti-hypertensive drug [116]. The major side effects of taste disturbances and skin rash were eliminated in most patients by the introduction of enalapril [117]. Several ACEi followed including benazepril, lisinopril, perindopril, quinapril, ramipril [65,118]. These

drugs are designed to inhibit the conversion of AngI to AngII and reduce activation of the AT₁ receptor subtype resulting in a sustained decrease in systemic blood pressure. It has been shown that captopril and perindopril influence not only the peripheral but also the central RAS [119]. Along these lines, mild to moderate male hypertensive patients treated with captopril indicated improved mental acuity, less sexual dysfunction and an improved sense of wellbeing [120]. Amenta and colleagues [121] reviewed clinical trials results concerning the influence of anti-hypertensive treatments on cognitive processing in hypertensive patients. They concluded that ACE inhibitors improved cognitive functioning independent of blood pressure effects and superior to β -blockers and diuretics. Further, ACE inhibitors have been reported to facilitate cognitive performance and reduce the occurrence of vascular dementia following hemorrhagic or ischemic cerebrovascular accidents.

Stabilization of cognitive performance by ACE inhibitors has also been noted in patients with Mild Cognitive Impairment (MCI) [122,123]. Hajjar et al. and others [124,125] have reported a slowed rate of cognitive decline in Alzheimer's Disease (AD) patients placed on ACE inhibitors. In contrast, Sudilovsky et al. [126] reported ceranopril to have no effect on cognitive functioning in AD patients; while Khachaturian et al. [127] found ACE inhibitors to be the only anti-hypertensive drug to indicate a slightly increased incidence of AD. For thoughtful reviews concerning the development of these drugs and their chemical structures and targets beyond cardiovascular disease the reader is referred to the following papers [65,83,128].

Diseases that Impact Memory and Cognition

Early on a role for AngII in the facilitation of memory and cognition was proposed [42,51,87,129-131]. However, subsequent animal studies indicated that intracerebroventricular delivery of AngII interfered with performance on most memory tasks used with animal models [12]. This finding agreed with reports that ARBs improved cognitive processing as mentioned earlier. But if AngII acting at the AT₁ receptor interfered with memory, and blockade of this receptor improved memory, what was the mechanism responsible for this memory facilitation? A majority of recent results point to AngIV interacting with the AT₄ receptor subtype as the source of memory improvement [13]. These collective results can be explained as follows. Blockade of the AT₁ receptor subtype prevents memory interference and permits unbound endogenous AngII to be converted to AngIV, which then binds at the AT₄ receptor. This notion is supported by the observation that ACE inhibitors enhance cognitive processing in both humans [123,132] and animal models [133]. The resulting increases in AngI levels due to inhibition of ACE are likely converted to Ang (1-9) to Ang (1-7) and then to Ang (3-7). Ang (3-7) has been reported to act as an agonist at the AT₄ receptor subtype [134]. AngIV analogs such as Nle1-AngIV, have shown promise in overcoming the memory impairments evidenced by several animal models of AD. Intracerebroventricular (icv) treatment with Nle1-AngIV reversed memory deficits due to: 1) application of the cholinergic muscarinic receptor antagonist scopolamine [135]; 2) kainic acid-induced lesions of the hippocampus [136]; 3) perforant path knife-cuts [136]; 4) embolic stroke due to carotid artery injection of microspheres [62]; and 5) ischemia resulting from transient four-vessel occlusion [137,138]. This latter finding is important given the strong possibility that cerebral hypoperfusion acts as a precursor

to the development of MCI followed by AD [139]. Consistent with these behavioral results [125] AngIV has been autoradiographically localized within structures known to mediate cognitive processing including neocortex, hippocampus, and the basal nucleus of Meynert [50,87,140].

Alzheimer's Disease

Patient numbers

Approximately 5.5 million people in the U.S. are diagnosed with Alzheimer's Disease (AD) [141,142] and more than 16 million worldwide [143]. In 2017 it is estimated that 6.08 million Americans were afflicted with AD. This number is predicted to reach 15 million by 2060 [144], and three times that worldwide [145]. Treatment and care costs for the U.S. patients is estimated at \$70-100 billion [146,147] and worldwide in excess of \$600 billion [148]. Without a breakthrough in treatment, these numbers of AD patients and associated costs may overwhelm our health care systems. There is also growing concern over concussion-induced cortical damage seen in children and adults who participate in contact sports such as American football (chronic traumatic encephalopathy), boxing, martial arts, and soccer, as well as our service men and women who have experienced combat associated concussions [149,150]. Evidence indicates that repeated concussions may encourage MCI [151].

FDA approved drugs

Despite intensive research efforts, only two categories of drugs have been approved by the FDA to treat AD, and only one in the past 20 years. Cholinesterase inhibitors such as Razadyne, Exelon, Cognex and Aricept disrupt the degradation of acetylcholine thus extending the half-life and availability of this neurotransmitter acting at central cholinergic muscarinic and nicotinic receptors [53,152-154]. A second approach utilizes an N-Methyl-D-Aspartate (NMDA) receptor antagonist, Namenda (memantine HCl), to limit glutamate excitotoxicity and resulting neuronal damage [152,155,156]. These drugs have demonstrated limited ability to delay the symptoms of AD and none prevent disease progression. However, both Roche and Eli Lilly have experienced monoclonal antibody A β drug failures in advanced clinical trials resulting in trial terminations [157,158]. Tau aggregation inhibitors are also being tested designed to discourage the formation of neurofibrillary tangles [159].

It should be noted that Biogen's controversial "plaque buster" monoclonal antibody drug to amyloid- β (A β), aducanumab (BIIB-037), was approved by the FDA in June 2021. However, the Scientific Review Committee voted to deny approval citing the presence of brain swelling, and some brain bleeds, in several clinical trials participants. This decision is currently under FDA review.

Biomarkers of alzheimer's disease

AD patients present extensive distributions of senile plaques and neurofibrillary tangles accompanied by neuroinflammation, oxidative stress-induced damage and a pronounced loss of synaptic connections predisposing neuronal apoptosis [160]. Plaques composition includes aggregates of amyloid-beta peptide (A β) due to a significant elevation in the production of neurotoxic A β (1-42) [161,162]. The A β (1-42) peptide oligomerizes resulting in neuronal toxicity. Neurofibrillary tangles are characterized by aggregated hyperphosphorylated tau protein. These proteins normally act to stabilize microtubules but in

AD patients, they contribute to a loss of neuronal structural integrity ultimately impacting synaptic connections.

The goal of providing an effective treatment for AD has been elusive in part due to the multifactorial characteristics of the disease process and difficulty in identifying reliable biomarkers [163-165]. Presently established diagnostic indicators of AD are present in other forms of dementia including frontotemporal, vascular, diffuse Lewy body, corticobasal, dementia due to Parkinson's disease and HIV infection, as well as normal aging [166-170]. It has been speculated that the pathology associated with AD may initiate many years prior to the occurrence of clinical symptoms [139,154,171]. Thus, considerable effort is being directed toward the development of early detection techniques via monitoring saliva, serum, cerebrospinal fluid, neuroimaging biomarkers, and behavioral measures of cognitive dysfunction [172-177]. Reliable detection at the earliest signs of AD related pathology could permit treatment many months or even years ahead of symptoms. Research must continue with the ultimate goal of preventing neuronal damage and preserving memory and cognitive functioning. However, efforts must also focus on the interim strategy to delay neuron losses in memory associated brain structures including the hippocampus, nucleus basalis of Meynert, piriform and neocortices. A drug designed to slow pathology, and thus major symptoms, would extend the patient's quality of life and significantly reduce health care costs. De la Torre [178] has calculated that delaying disease onset by 5 years would reduce the number of diagnosed patients by upwards of 50%.

Parkinson's Disease

Symptoms and treatments

James Parkinson first described this disease in 1867 and Parkinson's Disease (PD) now affects approximately 1.5% of the world's population over 65 years of age [179]. PD is characterized as a progressive loss of brain Dopaminergic (DA) neurons in the substantia nigra pars compacta. The striatum is the primary projection field of substantia nigra DA neurons. The loss of DA synthesis and release results in insufficient stimulation of dopaminergic D₁ and D₂ receptors throughout the striatum [180-182]. Decreased availability of DA triggers a triad of symptoms including bradykinesia, tremors-at-rest, and rigidity. Discussion continues over the pathogenesis of PD with arguments in favor of both genetic and environmental factors. There is growing evidence from animal models and PD patients that neuroinflammatory processes, likely triggered by reactive oxygen species, damage mitochondrial membrane permeability, enzymes and mitochondrial genome, leading to DA cell death [183,184].

Levodopa (L-DOPA) has been shown to be effective at controlling motor symptoms in the majority of patients but is ineffective regarding non-motor symptoms. Current treatment strategies to relieve motor symptoms include DA replacement via L-DOPA (the precursor of DA), DA receptor agonists, monoamine oxidase B inhibitors, and catechol-O-methyltransferase inhibitors (to protect the DA that is formed). As the disease progresses periods of decreased mobility, dyskinesia, and spontaneous involuntary movements complicate treatment (Marsden, 1982). These motor dysfunctions are currently treated with the DA receptor agonists apomorphine and levodopa, and surgical techniques including pallidectomy and deep brain electrical stimulation [185-187]. Progressive DA neurodegeneration

may also impact additional non-dopaminergic neurotransmitter systems including noradrenergic, cholinergic, and serotonergic [188]. As a result, non-motor symptoms may develop including depression, sleep disturbances, dementia, and autonomic nervous system failure [189-191]. L-DOPA continues to be the most efficacious oral delivery treatment for the control of motor symptoms [192]. Unfortunately, L-DOPA is reasonably ineffective at combating non-motor symptoms [189]. Thus, current research efforts are directed at controlling these additional symptoms, as well as the development of new strategies designed to offer neuroprotection and overall disease reversal benefits. Attaining the goals of slowing and hopefully reversing the rate of DA neuron loss may also result in the protection of non-DA neurotransmitter systems.

The RAS and parkinson's disease

A relationship between the brain renin-angiotensin system and Parkinson's disease was first suggested by Allen and colleagues [193]. These researchers measured decreased angiotensin receptor binding in the substantia nigra and striatum in post mortem brains of PD patients. This can be explained by the fact that in addition to the systemic RAS described earlier there are local RASs present in many tissues including the brain [194]. These local systems also synthesize angiotensins that mediate the action of many substances including cytokines and growth factors involved in cellular growth, apoptosis, and inflammation [195,196]. Locally formed AngII binding at AT₁ receptors activates Nicotinamide Adenine Dinucleotide Phosphate (NADPH)-dependent oxidases that are a source of superoxide (O₂⁻) which is upregulated in diabetes, hypertension and atherosclerosis [197-201]. Activation of the AT₁ receptor also results in the synthesis of chemokines, cytokines, and adhesion molecules, all important in the migration of inflammatory cells into regions of tissue injury [202]. Autoradiographic studies have identified AT₁ receptors in substantia nigra DA neuron cell bodies and terminal fields in the striatum in a number of mammalian species including humans [16,203,204], with humans evidencing the highest levels [193].

Several studies support an important role for ACE in PD. ACE is present in the nigra-striatal pathway and basal ganglia structures [205-207]. PD patients treated with the ACEi perindopril showed improved motor responses to the DA precursor 3,4-dihydroxy-L-phenylalanine [208]. Relative to treatment with perindopril, elevated striatal DA levels were measured in mice [209]. ACE inhibitors have been shown to inhibit bradykinin metabolism and thus modulate inflammation and induce blood vessel dilation [210], which are key factors in neurodegeneration. Activation of the AT₁ receptor subtype by AngII activates NADPH-dependent oxidases, a significant source of reactive oxygen species [45,211]. Treatment with ACE inhibitors has been shown to offer protection against the loss of DA neurons in 1-Methyl-4-Phenyl-1,2,3,6-Tetrahydropyridine (MPTP) animal models [209,212], as well as the 6-OHDA rat model [213]. The likely mechanism underlying this ACEi-induced protection is a reduction in the synthesis of AngII acting at the AT₁ receptor subtype [214,215].

In light of the above reports, it follows that if AngII activation of the AT₁ receptor subtype results in facilitating the NADPH oxidase complex and the formation of free radicals, then blockade of the AT₁ receptor should serve a protective function. This appears to be the case given that treatment with AT₁ receptor antagonists have been

shown to protect DA neurons in both the 6-OHDA [216] and the MPTP-models [217]. AT₁ receptor antagonists have been shown to reduce the formation of NADPH oxidase-derived reactive oxygen species following administration of 6-OHDA. A recent study designed to evaluate the relationship between treatment with anti-hypertensive drugs and the risk of developing a first-time diagnosis of PD, found no association with ACE inhibitors or AT₁ receptor antagonists, while treatment with calcium channel blockers was associated with a reduced risk of Parkinson's disease diagnosis [218]. It should be noted that there may be methodological concerns with this investigation [219].

A potential role for AngIV and the AT₄ receptor in PD has been investigated [220]. A genetic in vitro PD model was used consisting of the α -synuclein over-expression of the human neuroglioma H4 cell line. Results indicated a significant reduction in α -synuclein-induced toxicity with losartan treatment combined with the AT₂ receptor antagonist PD123319, in the presence of AngII. Under these same conditions, AngIV was only moderately effective. However, these authors did not use a metabolically stable AngIV analog nor did they employ an AT₄ receptor antagonist in combination with AngII or AngIV.

In summary, experimental work suggests that treatment with an AT₁ receptor antagonist may offer some protection against the risk of developing Parkinson's disease [214]. However, results from an observational study concerning antihypertensive treatment and the risk of Parkinson's disease were disappointing regarding treatment with ARBs and ACE inhibitors [218]. Much additional work must be conducted to better understand the relationship among brain angiotensin receptors and ligands, neuroinflammation and reactive oxygen species, as related to Parkinson's disease.

Relationship Among RAS, Hepatocyte Growth Factor and Parkinson's Disease

Neurodegeneration and aging

Aging represents a major risk factor in predisposing individuals to neurodegenerative diseases [221-223]. The neurodegeneration accompanying aging is dependent in part upon oxidative stress, neuroinflammation, and microglial NADPH oxidase activity. Each is of significant importance regarding DA neuron loss [224,225]. Activation of AT₁ receptors by AngII has been shown to facilitate DA neuron degeneration by activating microglial NADPH oxidase [225]. The activation of AT₁ receptors by AngII failed to cause DA neuron degeneration when microglial cells were absent [211]. Of related importance, Zawada and colleagues [226] recently reported that nigral dopaminergic neurons respond to neurotoxicity-induced superoxide in two waves. First, a spike in mitochondrial hydrogen peroxide was measured three hours following treatment with an MPTP metabolite (MPP+). Second, by twenty-four hours following treatment hydrogen peroxide levels were further elevated. Treatment with losartan suppressed this nigral superoxide production suggesting a potentially important role for ARBs in the treatment of PD. Further, AngII binding at the AT₁ receptor increased DA neuron degeneration initiated by subthreshold doses of DA neurotoxins by stimulating intra-neuronal levels of Reactive Oxygen Species (ROS) and neuroinflammation by activation of microglial NADPH oxidase [199,201,227,228].

AT₁ receptor subtype blockade

From the above observations it follows that AT₁ receptor blockade should have a neuroprotective effect on DA neurons in PD patients as demonstrated in animal models [217,220]. Less obvious is the likelihood that AT₁ receptor blockade results in accumulating levels of AngII which is converted to AngIII and then to AngIV. This conversion cascade has been shown to occur intracellularly [229]. In fact, this conversion of AngII appears to be necessary for DA release to occur in the striatum [230]. Thus, an intriguing alternative explanation concerning these AT₁ receptor antagonist results is that the increased endogenous levels of AngIV facilitate activation of the HGF/Met receptor system and in turn neuroprotection of DA neurons. In this way AngIV may act, in combination with AT₁ receptor blockade, to protect DA neurons.

In agreement with the above hypothesis, HGF has been shown to positively impact ischemic-induced injuries such as cardiac [231] and hind limb ischemia [232,233]. HGF has also been shown to eliminate hippocampal neuronal cell loss in transient global cerebral ischemic gerbils [234], and transient focal ischemic rats [235]. Date and colleagues [236] have reported HGF-induced improvement in escape latencies by microsphere embolism-cerebral ischemic rats using a circular water maze task. These authors measured reduced damage to cerebral endothelial cells in ischemic animals treated with HGF. Shimamura et al. [237] have shown that over-expression of HGF following permanent middle cerebral artery occlusion resulted in significant recovery of performance in the Morris water maze and passive avoidance conditioning tasks. Treatment with HGF was also found to increase the number of arteries in the neocortex some 50 days following the onset of ischemia.

In sum, these results suggest a role for the HGF/Met receptor system in cerebroprotection and are consistent with the notion that AngIV increases blood flow by a NO-dependent mechanism [238]. There have been reports of increasing doses of AngIV via the internal carotid artery significantly decreasing mortality and cerebral infarct size in rats twenty-four hours following embolic stroke due to the intracarotid injection of calibrated microspheres [137]. Pretreatment with the AT₄ receptor antagonist Divalinal, or N ω -Nitro-L-Arginine Methyl Ester (L-NAME), abolished this protective effect. Sequential cerebral autoradiography indicated that AngIV caused the redistribution of blood flow to ischemic areas within a few minutes. Thus, AngIV may yield its cerebral protective effect against acute cerebral ischemia via an intracerebro-hemodynamic Met receptor-mediated NO-dependent mechanism.

Type 2 Diabetes

Case numbers

At present, there are approximately 29 million diabetic patients in the U.S. with 1.4 million new cases diagnosed each year. Of these 90% are Type 2 leaving the remainder as Type 1. World-wide the number of Type 2 diabetic patients is estimated to be 380 million (International Diabetes Federation) [239]. This number is anticipated to increase to 430+ million by 2050. Over time a significant number of these patients, perhaps as high as 10%, will develop AD-like symptoms [240-242]. Both Type 2 Diabetes (T2D)-induced dementia and AD are now considered "metabolic diseases" in that they evidence impairments in insulin responsiveness and glucose utilization. In the

case of AD this impaired response to insulin encourages, in part, brain inflammation, oxidative stress, the accumulation of β -amyloid protein within neurons, tau hyperphosphorylation, and the loss of synaptic connections resulting in neuronal apoptosis in memory-related structures [243-246]. Hallmarks of T2D include brain insulin resistance and impaired insulin signaling that can initiate abnormal glucose metabolism, inflammation and oxidative stress responses, mitochondrial dysfunction, and vascular damage [241,244]. Thus, T2D and AD patient's exhibit common biomarkers and the resulting T2D-induced cognitive impairments create long-term consequences with similar impacts on the patient, family members, care givers, and health care providers as AD [240,247]. Since T2D and AD patients share many biomarkers, and the presence of T2D accelerates the possible onset of AD-like symptoms [240,241], it is reasonable to look for predisposing factors common to both diseases. An overlooked contributor to the metabolic dysfunction seen in both AD and T2D is the role of the RAS. An argument can be made that T2D is facilitated by the onset of organ vulnerability to diabetic-induced hyperglycemic injury and over activity of local RASs [248-250].

AngII levels and oxidative stress

It has been known for some time that hyperglycemia induces oxidative stress; however, elevated AngII tissue levels have also been shown to act as an oxidative stress-inducer [251,252]. Thus, elevated AngII concentrations in diabetic tissues may exacerbate hyperglycemia-induced oxidative stress damage [248,249]. As a result, oxidative stress appears to both underlie, and be the result of, patho-biochemical mechanisms of diabetic-induced tissue damage [250]. For example, the retina and kidney have been reported to have over-active local RASs during episodes of hyperglycemia [253-255]. Elevated pro-renin levels have been measured in the vitreous of the eye in diabetic patients with proliferative retinopathy [256]. Some older patients with this disorder evidenced increased vitreous AngII levels [257]. Further, there is evidence that vitreous AngII levels are positively correlated with the degree of retinopathy [256]. There is a strong correlation between organs vulnerable to diabetic-induced hyperglycemic injury (e.g. kidney and retina) and the over activation of local RASs [258,259]. Increased AngII concentrations in these tissues appear to promote end-organ damage in at least two ways: 1) by activating AT1 receptor proteins thus inducing changes in local blood flow and tissue hydration; and 2) exacerbating hyperglycemia-induced oxidative stress, elevated polyol and hexosamine pathway variability, and facilitating glycation end-products. Thus, the use of drugs to inhibit the RAS has become an important treatment approach to control diabetic nephropathy, and to a lesser extent retinopathy.

In support of this hypothesis is the finding that the inhibition of the RAS with ACE inhibitors, or ARBs, in diabetic nephropathy rats reduced oxidative stress [16]. Several clinical trials have evaluated the efficacy of RAS blockade with diabetic patients. One noteworthy trial focused on young Type 1 diabetic patients evidencing vascular superoxide overproduction (an early sign of angiopathy) due to hyperglycemia-related dysfunctional intracellular antioxidant enzyme production [260]. This dysfunction was reversed by treatment with the ARB irbesartan. Further, the ARBs candesartan and R-147176 (a sartan with low affinity for the AT₁ receptor subtype) appear to exert direct antioxidant influences presumably independent of AT1 receptor blockade [261]. Thus, these drugs show promise with regard

to protecting against diabetic-induced end-organ damage. However, they do not protect against T2D-induced dementia.

Type 2 diabetes and dementia

The diagnosis of T2D presents a major risk factor in the development of dementia. Type 2 diabetes is generally associated with aging and occurs at the rate of 20% in people over 65 years of age [246,262]. As previously indicated T2D is characterized by a number of metabolic disorders including cellular insulin resistance, compromised glucose utilization, and chronic inflammation. These dysfunctions facilitate cellular damage to kidneys, eyes, vasculature as in coronary artery disease, neuropathy and other end-organ damage [244]. The recognized metabolic syndrome associated with T2D include hyperinsulinemia, hypercholesterolemia, and hyperglycemia may encourage brain neuron losses resulting in structural atrophy. In addition, these neuronal pathologies are shared with AD patients [244]. It has been estimated that T2D patients may suffer a two-fold increase in the life time risk of dementia [263]. At least 10% of the current world-wide population of T2D patients evidence dementia characteristics. An intensive evaluation of 100,000+ cases of dementia revealed that the presence of diabetes resulted in a 60% increased risk of dementia in both men and women [264]. The relative risk of vascular dementia for T2D diagnosed women was 2.34-time controls, and 1.49 for men. The risk of nonvascular dementia was elevated 1.53 for women and 1.49 for men. These analyses argue that world-wide there are an additional 30+ million T2D dementia patients to be added to the 47 million AD patients [265].

It has now become accepted that the treatment of T2D patients with ACE inhibitors or ARBs reduces activation of the RAS with resulting reductions in hypertension and oxidative stress, and also impacts local HGF/Met receptor systems. Along these lines treatment with an ACE inhibitor reduces the formation of AngII; however, the resulting increase in the nonapeptide, D-Asp1,AngI, leads to the cleavage of aspartate by APA, followed by conversion to AngIII with the cleavage of histidine and leucine via carboxypeptidases activity, and then to AngIV via APN cleavage of arginine [21]. This resulting elevation in circulating AngIV levels activates dimerization of HGF followed by increased binding at the Met receptor thus optimizing hepatic and cellular insulin responsiveness. A similar outcome would be anticipated with ARB treatment of T2D patients. Thus, the positive response of T2D patients treated with an ARB [19,20,65] may be due to an excess of AngII that cannot bind at the AT1 receptor subtype. This excess AngII is converted to AngIII, and then to AngIV and Ang (3-7). Both AngIV and Ang (3-7) are capable of facilitating dimerization of HGF, which then activates Met receptors in the pancreas and elsewhere. Activation of Met receptors in turn increment insulin production and facilitate cellular insulin responsiveness, with accompanying reductions in hyperglycemia-induced oxidative stress and end-organ damage. Unfortunately, these elevations in AngIV and Ang (3-7) do not prevent T2D-induced dementia. Our best guess is that both AngIV and Ang (3-7) have difficulty penetration the BBB and thus are not significantly impacting the brain. In addition, members of our laboratory determined years ago that the half-life of AngIV is in the range of 10-20 seconds. We did not know about the importance of Ang (3-7) at that time so did not test it.

In summary, a relationship exists between the development of Type 2 diabetes and the likelihood of neurodegeneration resulting

in Alzheimer's disease-like symptoms. A complete understanding of the factors underlying this neuropathology has not been forthcoming. However, it appears that components of the RAS, specifically the AngII/AT₁ receptor system, are activated by T2D, and in turn contribute to processes characteristic of AD including neuroinflammation, oxidative stress, reduced cerebral blood flow, destructive tissue remodeling and damage to the cellular mechanisms underlying memory consolidation and retrieval. These same pathologies have been identified in patients afflicted with T2D-induced dementia [240], and a role for the RAS has been suggested [246]. An AngIV analog may be an effective treatment for T2D-induced dementia [54]. This suggestion is bolstered by the finding that the HGF/Met receptor system has been identified as important in diabetes [266,267].

Depression and Neuroinflammation

Major depressive disorder

Major Depressive Disorder (MDD) is a common form of mental disorder affecting approximately 15% of the U.S. population at least once during lifetime [268]. Approximately 17 million American adults experience one or more episodes of depression in a year [269]. In addition, episodes of depression are experienced by about 2% of children and 5% of adolescents [270]. The likelihood of depression increases with age particularly among those with functional disabilities, and/or physical and cognitive illness [271-273]. About 10% of community/residence-seniors report symptoms of major depression [272,273]. The pathophysiology of adult depression is complex with contributing factors that include CNS and peripheral systemic factors, while Alzheimer's disease, Parkinson's disease, stroke, alcohol/drug addiction, and other chronic diseases, are recognized risk factors [274-276]. In particular, cancer, cardiovascular disease, metabolic and endocrine dysfunction are often associated with depression [277,278].

RAS and depression

The first suggestion that the brain RAS is important in depression came with the observation that captopril induced an anti-depressant effect in hypertensive patients that also suffered from depression [279-282]. There had been previous hints concerning this relationship from animal studies. Specifically, rats treated with antidepressants revealed decreased water intake induced by peripherally or centrally injected isoprenaline, either in the presence or absence of a α_2 -adrenoceptor antagonist [283,284]. Further testing indicated that each of the antidepressant drugs fluoxetine, desipramine, and tranylcypromine, reduced AngII-induced dipsogenicity in rats [285,286].

Captopril treatment has also been shown to protect animals against the forced swim induction method of learned helplessness-induced depression. This protocol requires the animal to swim within a small pool of water that has no escape. Eventually the animal stops swimming and becomes immobile. The next day it resumes swimming and becomes immobile significantly sooner than during the initial trial. In each subsequent test day, the latency to evidence immobility decreased, i.e. "learned helplessness". Pretreatment with captopril reduced immobility by mice equivalent to treatment with the antidepressants imipramine or mianserine [287]. Learned helplessness induced by foot shock in rats could be prevented by pretreatment with captopril to the same effect as imipramine [288]. Under both protocols the

protective effects of captopril were reversed by naloxone, suggesting that the ACE inhibitor was exerting its antidepressant effects, at least in part, via opioid receptors. In addition, this effect is also dependent upon the brain RAS since pretreatment with losartan provided protection from immobility in the forced swim test [289,290]. These results suggest that antidepressants exert their positive effects to some degree by inhibiting the brain RAS. The precise mechanism(s) of this inhibition remains to be determined. There is recent evidence that the chronic infusion of AngII may facilitate depression in adult C57BL/6 mice [291]. These animals were prepared with subcutaneous osmotic pumps and infused over a 21-day period. The mice evidenced depression-like behaviors when tested using forced swimming and tail suspension tasks. This depressive state could be reversed with imipramine or telmisartan. The authors hypothesized that AngII acts via microglia activation of the hippocampal-pituitary-adrenal axis, coupled with pro-inflammatory effects. They recognized that AngII does not readily cross the blood-brain barrier suggesting that it may be binding AT₁ receptors located within circumventricular organs that are fenestrated permitting entry of larger molecules. The authors also indicated that peripherally infused AngII may activate AT₁ receptors in the paraventricular nucleus of the hypothalamus. These issues must be resolved. One very important potential contributor to these depression-like behavioral responses is sustained elevations in blood pressure. Since blood pressure was not measured in this study, there is no way to determine whether systemic blood pressure reached hypertensive levels sufficient to cause lethargy in the treated mice. Even so these results are of potential importance and will require additional testing.

Identifying reliable biomarkers of depression has been challenging [292-294]. Many hypotheses have been posited to explain adulthood depression including alterations in glucocorticoid regulation and related stress hormones [295], insulin resistance [296], inflammatory chemokines and cytokines [297,298], and various trophic factors that are stimulated with injury, illness as well as other stressors [299]. Along these lines, accumulating evidence suggests that depression accompanying diabetes mellitus significantly increases pro-inflammatory mechanisms and a loss of hippocampal neuroplasticity [300-302]. The antidepressant medications presently available (5-hydroxytryptamine and norepinephrine-selective reuptake inhibitors) lack effectiveness in upwards of 50% of patients and typically require weeks of run-up treatment when effective [303].

Hippocampal and prefrontal cortex volume reductions

Post-mortem brain scans of depressed patients indicate significant reductions in the volume of limbic brain structures, most notably hippocampus and prefrontal cortex [304,305] two structures involved in memory and cognitive processing. Similar volume reductions (by MRI) have been measured in living MDD patients with severity depending on the progression of illness, duration and number of depressive episodes, and resistance to treatment [306]. Profound decreases in network connectivity have also been reported including decreases in intra- and inter-hemispheric functional connections. These results have been substantiated by a number of research groups [307-309] and have led to the notion that MDD should be categorized as a network dysfunctional disease [310]. Of particular importance, exposure to stress has been linked with neuronal atrophy and loss of glia in both structures [311,312]. Neurogenesis in the adult brain

is known to occur in the sub-granular zone of the dentate gyrus of the hippocampus and subventricular zone of the lateral ventricles [313,314]. Neural stem cells in these structures are capable of dividing asymmetrically to form a daughter stem cell and a rapid multiplying progenitor cell. If appropriately stimulated these progenitor cells mature into neurons that integrate into functional neuronal networks [315,316]. Chronic stress-induced depression decreases neurogenesis; however, treatment with antidepressant drugs may reverse this process [311,317,318].

Neurotrophic growth factors

These observations point to the involvement of dysfunctional hippocampal plasticity in the neuropathology of depression, with particular focus on neurotrophic growth factors. The “neurotrophic hypothesis” of depression suggests that depression results from decreased neurotrophic growth factor activity causing atrophy of neurons in the hippocampus and prefrontal cortex, coupled with decreased neurogenesis and loss of glia. It has been hypothesized that treatment with antidepressant drugs interferes with, and/or blocks, neurotrophic factor deficits thus reversing atrophy [311-314]. The neurotrophic growth factors thus far linked with depression include Vascular Endothelial Growth Factor (VEGF), fibroblast growth factor-2, and insulin-like Growth Factor (IGF-1), with particular interest in Brain-Derived Neurotrophic Factor (BDNF) [319-323]. BDNF appears to be necessary for a positive response to treatment with antidepressant drugs [311,324]; however, preclinical results concerning the role of BDNF depletion in the etiology of depression are less consistent. BDNF-deletion mutant mice generally reveal normal behavior when tested for depression although conditional female mutant mice have been reported to show increased immobility during forced swim testing [325]. The use of RNA interference to knock down BDNF expression in hippocampal substructures results in depression as measured using forced swim and sucrose preference tasks [326]. Liu and colleagues [327] used a knock-in mouse prepared with human BDNF Val66met polymorphism in order to decrease trafficking of BDNF mRNA to dendrites. This resulted in reduced spine density and diameter and reduced synaptogenesis in the prefrontal cortex. Ketamine-induced synaptogenesis was impaired in these mice suggesting that synaptogenesis is dependent on dendritic translation/release of BDNF. In addition, the ketamine related antidepressant response seen in the forced-swim test was blocked. Human polymorphism in the BDNF gene appears to be carried by approximately 30% of the general population and is associated with mild cognitive deficits and depression. AngIV analogs acting at the Met receptor promotes synaptogenesis, neurogenesis and counters neuroinflammation. This approach may reduce the neuropathology and prevent neuron losses in the hippocampus and prefrontal cortex.

Neurodegenerative Diseases of the Eye

Approximately 3 million Americans have been diagnosed with glaucoma and 80 million worldwide. The overall number of patients is anticipated to reach 111 million by 2040 [328]. There are 11 million macular degeneration patients in the U.S. and this number is predicted to be 22 million by 2050. Worldwide there are about 196 million patients, predicted to approach 288 million by 2040 [328]. Diabetes is responsible for a significant number of new cases of retinopathy (12,000 to 24,000 cases) each year [329]. Currently

there are 7.7 million Americans with diabetic retinopathy, a number expected to reach more than 14 million by 2050 [330]. Taken together these diseases represent the major reasons for blindness in the U.S. and around the world.

As previously discussed, several organs possess local renin-angiotensin systems. This is true of the eye [331,332]. Major contributors to these diseases include increased Intra-Ocular Pressure (IOP), decreased retinal microvascular blood flow, tissue inflammation and oxidative stress [333]. The role of the local RAS of the eye will be discussed with respect to each of these biomarkers and related diseases.

Glaucoma

The RAS of the eye is a major regulatory factor in the normal maintenance of IOP. Continuous adjustment is necessary regarding Aqueous Humor (AH) flow. Optimal IOP is required in order to maintain the normal shape of the eye and in turn optical and refractory properties. AH is produced by the ciliary body [334] and exits the anterior chamber via the trabecular, uveoscleral and uveolymphatic pathways [335]. AH flow through the trabecular meshwork, the endothelial lining of Schlemm’s canal, and finally collateral channels and aqueous veins into the circulation [336-338]. This flow appears to be driven by the pressure gradient of the IOP [339-344]. The resistance against outflow yields an IOP of approximately 15 ± 5 mm Hg [334,345,346]. This value can vary depending on physical exercise [336,347-349], sleep, changes in posture [350], aging and disease [335].

The optic neuropathy caused by untreated glaucoma leads to death of retinal ganglion cells and neurons thus impacting vision [351,352]. This disease can be difficult to diagnose given that not every patient evidences an elevated IOP, and not all patients with an elevated IOP necessarily develop glaucoma [353]. However, at present of the known risk factors IOP is of major importance and pressure reduction procedures have been shown to slow disease progression [354-358]. These include topical medications, laser therapy and surgical intervention such as shunts designed to lower IOP by increasing AH outflow or procedures to decrease the formation of AH.

Igic and colleagues [359] were the first to measure the presence of ACE activity in retinal homogenates. Since that discovery all of the major components of the RAS have been isolated in the eye including AngII, Ang (1-7), ACE2, the AT₁ and Mas receptors [331,360-362]. Given that the “blood-ocular” barrier discourages penetration by AngII, ACE and aldosterone it has been concluded that the eye possesses an intrinsic local RAS [363]. A number of investigators have proposed that this intrinsic system is important regarding the maintenance of IOP [332,364,365]. Related to this glaucoma patients, as well as animal models, placed on ACE inhibitors or ARBs evidence decreased IOP [366-372]. Glaucoma patients treated with the ARB losartan revealed significant drops in IOP via increased AH outflow regardless of whether they were initially hypertensive or not [368]. Further, topical application of Ang (1-7) also reduced IOP and this effect could be prevented by the Mas receptor antagonist A-779, suggesting that it was dependent on the Ang (1-7)/Mas receptor system [373]. There is also the claim that Ang (3-4) can inhibit ACE resulting in an increased level of AngI that is converted to Ang (1-

7) by ACE2 and exerts a protective influence [374]. Some years ago, James Fitzsimons and others investigated the pressor potency of several centrally applied angiotensins [375-377]. They reported the greatest pressor activity to intracerebral injected AngII followed by AngI and AngIII (picomol range), with less activity induced by Ang (3-8), (4-8), (5-8), and (6-8) (nmol range). The C-terminal dipeptide AngII (7-8) and other dipeptides were inactive. Given that Ang (3-4) is a dipeptide with a peptide bond that is vulnerable to degradation in vivo, the half-life of Ang (3-4) is likely very short, casting doubt on the clinical usefulness of this peptide. However, additional testing is necessary to determine whether these results can be replicated.

Macular degeneration

Age-Related Macular Degeneration (AMD) is a neurodegenerative disease resulting in the progressive loss of photoreceptor retinal pigment Epithelial Complex (RPE) cells [378]. As this occurs there is the observable accumulation of extracellular material called drusen at the interface of the RPE and the inner collagenous zone of Bruch's membrane. The detection of drusen within the macula of the eye is a definitive sign of AMD. The risk factors for AMD are many and include aging, genetics (offspring of AMD parents have a 3- to 6-fold increased risk as compared with the general population), smokers (greater than 40 years of smoking increases the likelihood by 2- to 4-fold), dietary intake of saturated fats, trans fats and omega-6 fatty acids [379], abdominal obesity also correlates, especially for men [380]. Chronic tissue inflammation is a recognized factor in AMD [381]. Although short term inflammation is very helpful to fight microbial infection and injuries, chronic inflammation can be very harmful, particularly as seen in neurodegenerative diseases. Finally, elevated oxidative stress and vascular insufficiency have been associated with inflammation, endothelial dysfunction and neuron degeneration in the retina [382].

There is a paucity of information concerning the potential role of the RAS in the etiology of AMD and yet there is overwhelming evidence that these local systems are instrumental in facilitating inflammation, increases in free radicals, coupled with vasoconstriction of local vessels [246]. As discussed, there are also angiotensin molecules capable of countering these deleterious factors including Ang (1-7) and small molecule AngIV analogs discussed in the next section.

Diabetic retinopathy

In general, the longer a patient has diabetes the greater the risk of developing Diabetic Retinopathy (DR) [383]. With non-proliferative DR the linings of retinal blood vessels are weakened resulting in microaneurysms. These bulges in the vessel wall often leak leading to swelling of the macula. With proliferative DR this condition advances to a critical point at which the retina is deprived of oxygen. In response new blood vessels form in the retina (angiogenesis) obstructing vision [384]. The tissue ischemia appears to trigger the production of growth factors such as VEGF. Diabetic animal models evidence increased retina levels of ACE, ACE2 and the AT₁ receptor protein [385-387]. Since AngII has a mitogenic influence on retinal endothelial cells in the retinal microvasculature, it is a prime suspect in stimulating the up-regulation of VEGF [388,389]. In addition, it is known that AngII stimulates Reactive Oxygen Species (ROS) formation [390,391] and ROS promotes retinal damage in DR. Along these lines, diabetic animals treated with ACE inhibitors, or ARBs,

evidenced reduced retinal microvascular damage, decreased vascular leakage, and reduced capillary formation and VEGF levels [392-395].

Human clinical trials to date have produced mixed results regarding the role of the RAS in the development of DR. One study reported that treatment with the ARB candesartan somewhat slowed retinopathy progression in Type 1 diabetic patients without hypertension [256,396-398]. A second study tested the combination of ACE inhibitors and a diuretic and found no impact on DR. It will be instructive to evaluate the efficacy of Ang (1-7), and the newly synthesized small molecule AngIV analogs, in the treatment of DR. These molecules should be tested by both oral and topical routes of administration.

Small Molecule Drug Development

Drug development targets

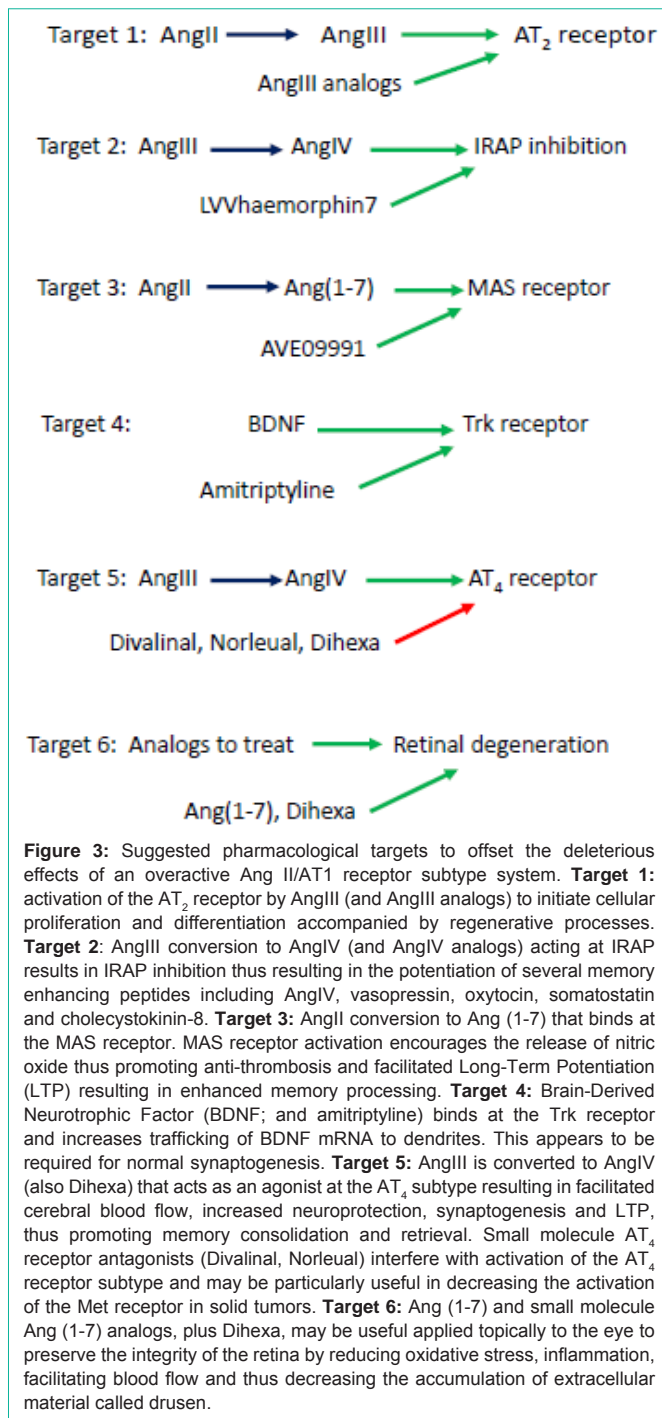

New targets must be considered in order to control the symptoms of neurodegenerative diseases and hopefully stop their progression. Clearly the RAS is a contributor and deserves particular attention. Basic characteristics of any drug candidate must include an extended half-life, the ability to protect vulnerable neurons in brain structures that mediate cognition, and the capacity to stop and perhaps reverse any damage. Additional specific criteria include the following: 1) the drug must penetrate the blood-brain-barrier in order to impact damaged brain structures. This is a major problem regarding most peptides and large proteins such as growth factors; 2) the half-life of the compound must be of sufficient duration to maintain a therapeutic level; 3) the avenue of drug delivery must be convenient for use by the patient and/or caregiver. This means oral, local application including cutaneous (patch) or subcutaneous (as with pen delivery) routes. Once the drug satisfies these challenges it would be desirable if it possessed the following neurological characteristics: 4) the capacity to encourage synaptogenesis, and promote stem cell proliferation, differentiation, and neurogenesis in impacted structures; 5) evidence neuroprotection especially against tissue ischemia, neuroinflammation and oxidative stress; 6) in the cases of dementia facilitate LTP, memory consolidation and retrieval, delay the onset of MCI and prevent concussion-induced encephalopathy. 7) With regard to the discussed eye diseases the drug candidate must protect the integrity of the retina and be delivered via convenient routes of administration.

Potential drug development approaches and targets

A first step in preventing the damage due to neurodegenerative diseases is to control hypertension with ARBs in order to block AT₁ receptors or ACE inhibitors to reduce the synthesis of AngII. There is a need to collect additional information on the beneficial cognitive effects of these drugs. However, those normotensive individuals at risk to develop symptoms of MCI and dementias are likely not candidates for treatment with ACEi or ARBs. Also, at present there is minimal information concerning the potential effectiveness of these drugs to limit symptoms and no evidence that they prevent the onset of dementias.

Target: AngIII agonists acting at the AT₂ receptor subtype

To date it is unclear whether the AT₂ receptor is present in sufficient numbers in brain structures associated with cognitive functioning to warrant clinical testing in AD patients. This may

change with additional research attention. An initial challenge concerns the design and synthesis of a non-peptidic AngIII agonist with an extended half-life that binds at the AT₂ receptor subtype (Figure 3).

Target: IRAP inhibitors

IRAP inhibitors (e.g. LVVhaemorphin7) have shown preclinical promise in enhancing memory on several tasks used to evaluate the performance of animal models [152,399]. Several specific inhibitors to IRAP have been developed that enhance spatial memory and fear

avoidance in animal models [152,400]. Anderson and Hallberg [65] have been particularly successful in designing and synthesizing a number of IRAP inhibitors. Also, IRAP knockout mice have been shown to suffer significantly reduced cerebral infarct volume 24 hours following a 2-hour transient cerebral artery occlusion as compared with wild type mice [401]. These results were attributed to an increase in compensatory cerebral blood flow during the occlusion process. The authors suggest that IRAP may be an important target regarding the treatment of ischemic stroke as well as AD.

Target ang (1-7) analogs acting at the MAS receptor

A promising approach particularly regarding local ocular application concerns increased activation of the Ang (1-7)/Mas receptor system. Ang (1-7) has been shown to stimulate the release of Nitric Oxide (NO) from vascular endothelial and smooth muscle cells thus opposing AngII and vasopressin-induced vasoconstriction [402,403]. This peptide also protects cardiac and endothelium functioning as well as coronary perfusion as demonstrated in heart failure models [404]. It is of interest that Ang (1-7) has been shown to facilitate baroreceptor reflex sensitivity and modulate circadian rhythm influences on heart rate and blood pressure [405,406]. It is well established that AngII promotes thrombosis primarily via expression of Plasminogen Activator Inhibitor 1 (PAI-1) [407,408]. Kucharewicz and colleagues [409,410] have reported that Ang (1-7) functions as an antithrombotic agent when administered to renal hypertensive rats that served as a venous thrombosis model. A major first step toward the use of this peptide to offset AngII's influence is the development of a non-peptidic Ang (1-7) analog, AVE09991 [411]. It would be very interesting to see the results of clinical trials designed to evaluate the efficacy of local application of this small molecule to glaucoma, macular degeneration and diabetic neuropathy patients.

Target: Neurotrophic analogs

There are few neurotransmitter, neuromodulatory or growth factor systems capable of satisfying the above listed drug development criteria and preventing dementia-associated dysfunctions. However, as earlier suggested neurotrophic agents possess characteristics that make them excellent candidates [13,76,80,246,412-414]. There are several neurotrophins capable of stimulating synaptogenesis, stem cell differentiation, neurogenesis, and neuroprotection against a wide range of cellular insults by facilitating anti-inflammatory and anti-apoptotic neuronal effects. These include NGF, BDNF, neurotrophin-3 and neurotrophin-4/5 [415-417]. Of these, BDNF has received considerable attention regarding depression and stress [418] and AD [176,412,416,419]. However, neurotrophins have had little success in clinical trials directed at neurodegenerative diseases due to their poor pharmacokinetic profile and large molecular weight that significantly impedes penetration of the BBB [420,421]. Jang and colleagues [421,422] have reported that the small molecule antidepressant drug amitriptyline is capable of binding to the Trk receptor, induce receptor dimerization, and autophosphorylation. As previously mentioned receptor, dimerization is a prerequisite to activation of neurotrophins and downstream signaling. Thus, the use of amitriptyline may serve as a "short-cut" past BDNF to receptor activation and have a positive impact against AD. However, at the present time this drug is being tested in clinical trials conducted with depressed and chronic pain patients, but not AD patients [423].

Target: AngIV analogs acting at the AT₄ receptor subtype

There is now substantial evidence that the brain AngIV/AT₄ receptor system is critically involved in memory formation and may overcome the memory inhibiting influences of AngII [54,55,87,131,424]. However, endogenous AngIV has a short half-life and thus appears to be over powered by AngII levels. In an effort to develop an AngIV, analog members of our laboratory initially synthesized a number of AngIV-based compounds possessing extended half-lives [425,426]. This resulted in the development of two potent receptor antagonists, divalinal-AngIV and norleual-AngIV [72,75,427-429], and one promising agonist, Nle1-AngIV. We determined that the memory facilitating effects of Nle1-AngIV derived from its N-terminal region given that fragments as small as tetra- and tripeptides retained the ability to overcome scopolamine-induced amnesia in animal models [73,87]. Further, Nle1-AngIV, as well as these shorter fragments, augmented hippocampal synaptic connectivity via the formation of new synapses [73]. Functionality of these synapses was established via evidence of analog-induced spinogenesis and the colocalization of synaptic markers in newly formed dendritic spines, which were coupled with enhanced miniature excitatory postsynaptic currents. These results encouraged the possibility that a clinically useful non-peptidic small molecule could be designed possessing increased metabolic stability with an extended half-life, and BBB penetrability offering facilitated cognitive functioning. Subsequent design and synthesis efforts yielded a small molecule with increased hydrophobicity, decreased hydrogen bonding potential, and significantly increased metabolic stability, dihexa. This compound induces spinogenesis/synaptogenesis at picomolar concentrations, is slowly cleared from the blood (plasma stability $t_{1/2} = 5-6$ hours) and can be delivered via parenteral routes of administration [76]. Dihexa binds with high affinity to HGF and stimulates dimerization, a prerequisite to binding at the Met receptor, and it induces Met phosphorylation in the presence of subthreshold levels of HGF. It also stimulates hippocampal spinogenesis and synaptogenesis equivalent with HGF [73,80]. Treatment with an HGF antagonist, "hinge", as well as a short hairpin RNA directed at Met, significantly inhibited these actions suggesting that these effects are due to specific activation of the Met receptor. Further, dihexa penetrates the BBB in sufficient quantity to facilitate memory consolidation and retrieval in the scopolamine-induced amnesic rat model of AD, as well as in aged rats employing the Morris water maze task of spatial memory [54].

Target: Topically applied drugs to treat retinal degeneration

Given results, indicating that ACE inhibitors and ARBs reduce ocular pressure the topical application of these drugs to glaucoma patients is worth evaluating. A clinical trial utilizing topically applied Ang (1-7) in glaucoma patients while monitoring ocular pressure and progression of retinal damage should be conducted. Regarding macular degeneration and diabetic retinopathy patients, topically applied Ang (1-7) and dihexa should be investigated with ongoing measurements of the same dependent measures.

Conclusion

Progress is being made concerning early detection of MCI. The development of new efficacious drugs to delay, and hopefully prevent, the onset of dementia symptoms must catch up with these efforts.

This will require a shift in our thinking. This shift is supported by the following observations from past findings: 1) β -amyloid-induced plaques and neurofibrillary tangles define AD but may not cause it. These cellular markers are likely consequential to other deleterious dysfunctions. 2) Efforts to develop drugs to rid neurons of amyloid plaque buildup have generally failed to improve cognitive processing. It is likely that current efforts to prevent neurofibrillary tangles will also fall short with regard to improved memory functioning. 3) Alzheimer's disease has a multitude of potential causes. These include, but are not limited to, genetic predisposition, neuroinflammation, head trauma, untreated hypertension, diabetes, Parkinson's disease, infection and normal aging. It may be necessary to attack each of these likely causes with separate drug development programs. 4) Presently available drugs do not promote synaptogenesis of existing neurons. The loss of synaptic connections discourages neurogenesis and is a major cause of neuronal apoptosis; 5) Current research must encourage efforts to develop drugs that penetrate the BBB, facilitate cognitive processing, and protect against the loss of synapses and neurons. 6) Neurotrophic agents offer the ability to facilitate synaptogenesis, neurogenesis and neuroprotection thus greater research attention must be directed toward creating small molecule analogs designed to penetrate the BBB and activate these brain systems. 7) It is likely that a successful approach to treating AD will require several different "Multiple Target-Directed Ligands" (MTDLs). Neurotrophic small molecule analogs may be useful in configuring such a strategy. 8) New drugs must be developed to treat glaucoma, macular degeneration, and diabetic retinopathy. With each disease, a major consequence is progressive retinal damage. The research presently summarized suggests that compounds designed to reduce the influence of the local AngII/AT₁ receptor system should be effective in controlling retinal damage in patients afflicted with these dysfunctions. Small molecule RAS related drugs designed to function as AT₁ receptor antagonists, followed by AngIV small molecule analogs that pass the blood-retina barrier, act to reduce oxidative stress, facilitate blood flow and stem neurodegeneration, are promising candidates as ocular treatments.

Declaration

Competing interest: Drs. Wright and Harding are the co-founders of M3 Biotechnology, Inc. (now Athira Pharma, Inc.) and hold stock in this company. No funds from this company were used to conduct the animal research presented in this manuscript or in its preparation. The authors are no longer actively involved in this company and have made every effort to objectively discuss the theories, findings and conclusions without bias regarding these topics.

Acknowledgements: All experiments utilizing animal models conducted in our laboratory and referred to in this review adhered to the Guidelines for the Care and Use of Laboratory Animals as required by the National Institutes of Health (NIH Publication No. 80-23), and the protocols were approved by the Washington State University Institutional Animal Care and Use Committee. The preparation of this paper was supported by the Michael J Fox Foundation, and the Alzheimer's Drug Discovery Foundation.

We have been privileged to benefit from conversations with, and conference presentations and papers by, insightful researchers interested in unraveling the mysteries and components of the renin-angiotensin system. These scientists included: Professors Merlin

Bumpus, Arthur C Guyton, William Ganong, James Fitzsimons, Detlef Ganten, Dominic Felix, James Fitzsimons, Mike Peach, Michael Brody, Alan Epstein, Ian Phillips, Fred Mendelsohn, Kim Johnson, Mark de Gasparo, Shigi Mitzutani and many others. Over the years, we have maintained a strong interest concerning the ever-increasing importance and complexity of the RAS, and anticipate this system to disclose many additional important functions and surprises in the future. We urge young neuroscientists to continue in the footsteps of these gifted researchers bringing enthusiasm and energy to the important task of discovering new functions of the renin-angiotensin system.
